The fact that heterosexuality is employed as a form of normative domination at the same time that it has largely escaped the gaze of scientific inquiry calls our attention to how public health can benefit from highlighting recent explorations of heterosexuality. Reproduction, gendered relations of power, masculine/feminine ideologies, marriage, and parenting have more recently begun to be explored at the intersection between sexuality and public health. In large part as a result of the HIV and AIDS epidemic, there has also been growing attention to what can be described as the political economy of heterosexual relationships: the ways in which economic exchange relations shape heterosexual interactions far beyond the context of what is traditionally understood as prostitution or sex work (Hunter 2002). The examination of the transactional nature of heterosexual relations has received special attention in sub-Saharan Africa as a result of research seeking to respond to the need for a fuller understanding of vulnerability in relation to the heterosexual transmission of HIV (Leclerc-

Madlala 2003), but is clearly an important, albeit highly variable, part of the organization of partner relations between women and men across widely varying social and cultural contexts that requires increased attention in seeking develop the field of sexuality in public health more broadly.

Another key area of research that focuses on heterosexual relations has been related to human procreation. According to the World Health Organization, reproductive health relates to having a 'responsible, satisfying and safe sex life and … the capability to reproduce and the freedom to decide if, when and how often to do so', safely, effectively, and affordably, and through access to health services (WHO 2011b). This discourse comes after decades of public health policies in countries throughout the world, such as those that supported the mass sterilization of women, with a focus on population control as a means to reduce poverty and increase economic growth. These 'structural' determinants of health severely limited women's sexual agency and sexual decision-making.

Moreover, in heterosexual partnerships these asymmetric gendered power dynamics occur not only at a structural level, but they also have effects on individual health outcomes for both women and men. Ideologies of masculinity have vast implications for public health outcomes globally. Preserving a sense of heterosexual manhood and invincibility has been a barrier to seeking health services (Gough 2013). This has been particularly challenging for public health movements advocating for prostate cancer screening, and heterosexual men are often more averse to anally invasive prostate exams (Gray et al. 2002). The concept of 'machismo' or male chauvinism has often been used to analyse the effects of Latin American heterosexual masculinity and its implications for health. Although studies on machismo have associated this ideology with sexual risk behaviours and intimate partner violence, the concept of machismo has been criticized for stereotyping Latino men (Torres et al. 2002). A more complex understanding of Latin American and Latino male sexuality shows that sexual behaviours are dependent on social and interpersonal context. Same-sex socialization among heterosexual men (Kandel and Davies 1991) has been linked to higher levels of sexual risk taking with women, drug use, and sexual violence.

At the same time, femininity has also shown to have effects on the health of women. Forms of the ideal 'sexy' woman certainly vary across the globe, among cultures, and often depend on social factors such as race and

ethnicity. However, there is an overwhelming prevalence of this context-dependent sexualized ideal, which even in its multiform instantiations has impacts on how women perceive themselves. The epidemics of eating disorders are of the clearest examples of how heteronormative femininity affects women's health. Public health research has shown that heterosexual women are affected by eating disorders such as anorexia nervosa and bulimia more so than non-heterosexual women (Meyer et al. 2001). Heteronormative femininity is a 'social determinant' of women's sexual health according to the Healthy People 2020's definition, which lists the factors that limit the 'availability of resources to meet daily needs, such as educational and job opportunities, living wages, or healthful foods', such as violence and discrimination (Healthy People 2020).

Furthermore, heterosexual relations, procreation, and partnerships often result in men and women taking on the responsibility of parenthood. Although parenting is not solely a heteronomative phenomenon in the current world order, public health studies have focused on the negative effects of single motherhood and absent fathers on the sexual and mental well-being of younger generations (Ishida 2010). For many, maintaining the institution of *heteronomative* marriage as both religiously and socially stable is a solution to potential health problems associated with heterosexual relations (Mahoney et al. 2008). However, more critical public health research has associated ideologies associated heteronormative marriage with infidelity, intimate partner violence, and sexual risk (Hirsch et al. 2007).

Sexual diversity and alternative sexualities

Framing sexual diversity in public health is methodologically and epistemologically complicated, particularly because of how sexual desires, behaviours, and identities converge and diverge. Recent cutting-edge global health research has shown that practices of categorization and classification across the axes of sexuality, gender identity, gender performance, and sexual role have been obscured by simplified models presented by social epidemiologists (Garcia et al. 2016a; Parker et al. 2016). Addressing sexual *identities* might be easier in social and behavioural research because there is more reliability in measures when the respondent identifies either to

themselves or openly to society about being a lesbian, gay, bisexual, transgender, or queer (LGBTQ) individual. Alternative sexualities go beyond identity, however, and a person who practices same-sex sexual behaviours or sex work might not identify with a particular group culture. It becomes even more complicated when speaking of desire that does not necessarily translate into behaviour or identity formation, as we mentioned earlier. Research questions vary depending on these dimensions of sexual diversity and alternative sexualities, and public health has often collaborated closely with social movements to set research agendas.

The broader framework of sexual health has been employed to study health problems related to populations characterized by sexual diversity (Parker et al. 2004). Much of the public health research has focused on behaviour change towards the practice of safer sex (e.g. through condom use and reduction in sexual partners), especially considering the disproportionately high impact of HIV and AIDS on gay and bisexual communities (Chow et al. 2011). Scholars have also focused on the intersections of mental and sexual health, using theories such as ‘minority stress’ to examine factors that affect depression, anxiety, and healthcare utilization (Meyer 2003). Fear of disclosure of having same-sex desires or of practising alternative sexualities, for instance, can have important implications on the ways people interact with their healthcare providers (Klitzman and Greenberg 2002). Sexual diversity interacts with other social factors, such as race and poverty, which lead to differential access to healthcare and exposure to disease (Díaz et al. 2001).

In the sexual health literature, there have been disputes over how to create epidemiological categories that capture sexual diversity. The categories of MSM, men who have sex with men and women (MSMW), and women who have sex with women (WSW), behaviourally bisexual, bisexual, gay, and non-heterosexual are all used in the field of public health depending on the research question involved. Some of these categories, such as MSM, attempt to capture self-identified gays and bisexuals as well as those who practice same-sex sexualities but that do not self-identify as gay or bisexual. The category MSM might strip away the social and political implications of public health work on alternative sexualities, which has been a prominent claim among public health activists. Categorizing populations such as MSM and WSW might be understood as an attempt to objectively perform science. Those advocating for LGBTQ health are part

of a public health social movement that understands non-heterosexuality as having vast variation in sexual performance central to a notion of well-being that hinges on social rights. The epidemiological use of categories such as MSM and WSW, among others, does not fully take into consideration that 'community, networks, and relationships in which same-gender pairings mean more than merely sexual behaviour', and these categories have been criticized by the public social movement as heterosexist (Young and Meyer 2005).

There has been less attention to the particular health disparities that affect lesbians and WSW in the public health literature (Bauer and Jairam 2008). This gap is probably due to the lesser impact that HIV and AIDS has had on these populations, when compared to other 'risk' groups. This has led to gaps in research for women who are vulnerable to HIV, although other sexually transmitted infections such as HPV (which causes cervical cancer in women) have been addressed in non-heterosexual women populations (Charlton et al. 2011). Bisexual women and women who have sex with women and men (WSWM) have had some attention particularly regarding their sexual health. There are important concerns about the unmet needs of lesbians, bisexual women, and WSWM in healthcare due to stigma and discrimination when seeking health (Stevens and Hall 1988). This is especially the case when they fear disclosing their sexualities. Lesbians and bisexuals have been identified as having a higher rate of cigarette smoking than heterosexuals in national studies (Ryan et al. 2001). The health concerns of lesbians are more proximal to those of heterosexual women (relative to comparing gay men with heterosexual men). However, non-heterosexual women encounter barriers in sexual and reproductive health, as well as in making important life decisions, such as childbearing that make them particularly vulnerable to stigma and discrimination (Dahl et al. 2013).

The mental and physical health of transgender men and women has drawn special attention in public health, especially in discussion about sex modification procedures, the formal classification of transgender individuals in the DSM and the ICD, and their access to health more generally (Lombardi 2001; Schwend et al. 2018). Illegal hormone and silicone injection has been of particular concern due to the high cost of gender transformation (Wiessing et al. 1999). Moreover, stigma and discrimination are probably most prevalent for transgender individuals,

limiting their employment and education opportunities. These are social aspects of their gender identities that directly affect their risk for HIV and AIDS and mental health problems, especially because many transgender women resort to commercial sex work because of their limited opportunities (Abdullah et al 2012). In some countries, such as Brazil and Cuba, public health policy debates about such government funding for gender modification are being couched in human rights frameworks and public health safety (Gorry 2010).

Moreover, male and female sex workers are among the most vulnerable populations for HIV infection, sexual violence, and drug use (Mayhew et al. 2009). The public health implications of sex work (and the shift to applying a human rights framework) have been explored through a variety of methods, including qualitative and ethnographic techniques. Innovative public health research and interventions have studied sexual risk and mental health risks throughout the world (Kempadoo 2003). Sex work, intergenerational sex, and gift-exchange for sex has been documented throughout the world, and it has been linked to factors such as food insecurity (Weiser et al. 2007). Progressive public health has shown that sex workers can no longer be thought to be merely victims, but have come to take on the role of the human rights advocates throughout the world pointing to the elements of structural stigma and discrimination that led to their condition.

It is a challenge to study sexual desire and behaviour in populations where assuming an identity puts the person at sociocultural, political economic, and even legal disadvantages. Because of the stigma and discrimination associated with non-heterosexual sexualities, non-politicized alternative sexual communities and/or individuals are often ‘hidden’ or hard-to-reach (Heckathorn 1997).

Public health studies and interventions on hidden population are among the most methodologically innovative. Snowball sampling or chain-referral sampling are common techniques in achieving a theoretically defined number of participants in qualitative research in fields such as anthropology and sociology. Respondent-driven sampling is a type of chain-referral sampling in which study participants refer others to the study, beginning with key informants or seeds that can be randomly selected. This form chain-referral provides a dual incentive for the participant and weights the sample. Respondent-driven sampling lends itself to social network analysis

if referral systems and patterns are tracked. In fact, this can be particularly useful in public health to study sexual networks, networks of drug users or sex workers (Ramirez-Valles et al. 2005). More researchers are beginning to bridge the gap between qualitative and quantitative approaches, as well as forging interdisciplinary perspectives, precisely because they acknowledge the complexities of studying sexual diversity in public health. It is now more common for studies with large probability samples to explore multilevel research questions that require a complimentary approach of ethnography and survey methods.

Social regulation of sexuality

The social regulation of sexuality impacts how public health studies are conceptualized, designed, and executed. A range of formal and informal institutions and community structures define socially accepted expressions of sexuality, delineating cultural and social psychological norms. Social regulation might occur to enforce moral 'tradition', especially when relating sexuality with heteronormative reproductive practices.

Legal frameworks are regulations with implications on sexual practices as well as on gender roles. Throughout the world, laws determine the ways in which sexuality affect economic and political issues, such as through the institution of marriage, which marginalizes non-heterosexuals. Laws that ban sodomy or that deny adoption privileges based on sexual orientation target non-heterosexuals and punish the unmarried. Legal systems also dictate who has control over the female body, what women are allowed to wear, how women are passed down as inheritance through generations of men in some countries, the kinds of sexual pleasure women should be granted, and in some cases laws sanction gender-based violence.

Social networks might regulate sexuality through 'soft' mechanisms such as gossip or 'harder' mechanisms such as ostracism from communities if non-conforming sexualities or gender roles are expressed. Families and schools are among the most important institutions in directly providing sex education for children and adults throughout the world. While families are often thought of as spaces for social support, conservative family values that condemn homosexuality, for example, might create structural vulnerabilities to mental health problems, including depression, substance

use, and thoughts of suicide among LGBT youth. Schools and their political agendas on sexuality vary, having a major impact on the sexual formation of the individual and her/his interaction with peers. Policy interventions, such as those that ban bullying in schools, might have vast implications public health outcomes.

Community-based groups and civil society organization such as faith-based organization have varied on their position on sexuality and public health. Some religious traditions, such as Pentecostal evangelicals—which have been proliferating in numbers throughout the world in the twentieth and twenty-first centuries, have been the most adamant proponents of public health campaigns that promote the reduction of sex partners, faithful relationships, waiting until marriage, among other more conservative approaches to regulating sexuality at the expense of excluding non-heterosexuals and gender non-conforming individuals from their messages and flocks. In research on Afro-descendent religion in countries such as Brazil, some faith-based organizations have shown to embrace alternative sexualities and sexual diversity, as well as have a strong platform for women's equality and rights (Garcia and Parker 2011).

Also noteworthy, the Internet is among the most influential social/virtual institutions in contemporary life that shape and regulate sexuality and sexual norms. The pornography industry is ever growing and few public health studies have systematically analysed the association between exposure to pornography and sexual behaviour, some finding that increased exposure to pornography is associated with higher sexual risk taking (Eaton et al. 2012). Social networks and smart phone applications (Apps) such as Grindr (which uses advanced GPS systems to locate proximal partners in the vicinity of the individual essentially to meet up and have sex) are often used to meet new sexual partners and fulfil sexual fantasies that were once only imagined. Even though the Internet has been more liberating than limiting in its forms of social regulation, conservative civil society groups are ever present on the worldwide web with moralizing, normalizing, and moderating tendencies that often make people afraid of having excessive sexual pleasure.

The public health implications of the social regulation of sexuality are extensive. Regulatory groups and mechanisms include not only legal frameworks, but also the family, schools, religious groups/institutions, formal community leadership structures, informal structures that generate

social (and virtual) capital, just to name a few, which have been considered important in public health studies and interventions related to sexuality. When considering the possibility of targeting sexual behaviours through community and ecological interventions and studies, we call for new methodologies that analyse both heterosexual and non-heterosexual practices and pleasures. For example, cellular phone technologies and innovative forms of ethnographic mapping that examines trends on virtual social networks on the Internet could amount to a greater understanding of how sexual desires are enacted. These can also be used to target vulnerable populations that might be excluded from participation in civil society organizations through self-selection or through social sanctioning.

Sexual health and sexual rights

The notion of sexual rights is the counterpart to social regulation. The emphasis on sexual rights has helped to constitute a fairly new to the field of public health and this framework draws on interdisciplinary and intersectoral approaches to improving collective health outcomes in what can be considered a public health social movement. Even though international mobilization has dominated the use of the term ‘sexual rights’ as a rallying framework in global activism, sexual rights are often only regulated effectively as they are interpreted and understood on the local level in families, at schoolyards, by community-based groups and non-governmental organizations (Garcia and Parker 2006).

The language of sexual rights in public health stems greatly from the application of a human rights framework to addressing not only individual, but also social and structural vulnerabilities. Human rights are general understood as universal and fundamental rights deserved equally by all people. The International Conference on Population and Development (ICPD) held in Cairo in 1994 was a watershed moment for the transnational dissemination of discourses of sexual rights, although the official document of the ICPD did not include in it a clear mention of the term sexual rights after much heated debate among conservatives and progressives (Petchesky 2000).

Although public health leaders have partnered with activists throughout the world to push for sexual equality to be considered part of our

fundamental rights, it has been difficult to include sexual rights as part of framing documents at the level of the United Nations because of their contentious nature. International discourses about reproductive and sexual rights have been rooted primarily in Western individualism, even though notions of bodily integrity and personhood have a long history in non-Western contexts, in which they are more intertwined with social and cultural norms and collective rights (Corrêa and Petchesky 1994). To address vulnerabilities that are contingent on context, culture, and structures, it is paramount to include access to resources and the community-level conditions that might enable or restrict sexuality and health.

Moreover, sexual rights emerged under the umbrella of reproductive rights (which focused primarily on gender inequality, violence against women, population control, among other heterocentric issues), but health rights activists and LGBTQ groups have pushed the envelope to develop a concept that goes beyond human reproduction and addresses non-heterosexual health and rights-based issues (Miller 2000). Although sexual health is often confounded with reproductive health, there has been an attempt to differentiate the two by the World Health Organization. These include the right of all persons, free of coercion, discrimination, and violence, to: ‘a state of physical, mental and social well-being in relation to sexuality. It requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences’ (WHO 2011a).

While sexuality can include all of these dimensions, not all of them are always experienced or expressed. The ‘responsible’ exercise of human rights requires that all persons respect the rights of others. Within the framework elaborated by the World Health Organization (WHO), sexual and reproductive health are central aspects of life at all ages and encompasses sex, gender identities and roles, sexual orientation, pleasure, and reproduction. Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles, and relationships. Sexuality-related vulnerabilities highlight why these issues ought to be framed as inextricably tied to other human rights, political and civil liberties, and economic rights (Parker et al. 2014).

The protection from harm, be it for heterosexual or non-heterosexual populations, has been the main focus of sexual rights movement (Parker et

al. 2013). Nonetheless, sexual pleasure has also been conceptualized as an integral part of sexual rights by activists and also by progressive public health campaigns. One example of harnessing the power of the sensual in social marketing is the eroticization of the condom. Rather than showing the condom in isolation as a prophylactic barrier to natural sex, campaigns throughout the world have used sex symbols to entice safer sex—almost as a form of harm reduction in which people are assumed to be having sex in any case, so these campaigns make 'safer', sexy. Sexual rights frameworks that are emerging throughout the world are giving birth to new debates about gender and sexual equality that goes beyond reproduction (not to downplay the utmost importance of debates about new reproductive technologies that are more inclusive of non-heterosexuals).

Conclusion

During the closing decades of the twentieth century and the beginning of the twenty-first, the field of sexuality and public health has taken shape as one of the fastest growing areas of research and intervention in relation to population health. It is a field that has been characterized historically as highly polemical, and frequently marked by controversy and disagreement based on conflicts in relation to fundamental values and ethical positions. But at least since the emergence of the HIV and AIDS epidemic in the early 1980s, we have also realized that ignoring issues of sexuality, sweeping them under the carpet or leaving them hidden away in the closet, does nothing to promote the realization of true sexual health and well-being. This is especially worrisome when sexual norms, as we have pointed out, lead to grave disparities in health. On the contrary, it is only by bringing sexuality out into the open, by freeing it of stigma, prejudice, and discrimination, and by building a culture of sexual rights, freedoms, and protections, that we can truly advance the cause of sexual health and well-being. In this sense, it is clear that public health work on sexuality in the early twenty-first century both grows out of and is aligned with the long tradition of public health as itself a social movement—a movement based on principles of social justice and human rights, capable of promoting health for all based on a foundational set of ethical and political principles. Far from a peripheral

concern related to a taboo topic, few areas of work are so central to a public health agenda for the present.

6.3

Demography and public health

Emily Grundy and Michael Murphy

Introduction

The health and healthcare needs of a population cannot be measured or met without knowledge of its size and characteristics. Demography is the scientific study of population and is concerned both with the measurement, or estimation, of population size and structure and with population dynamics—the interplay between fertility, mortality, and migration which determines population change. These are pre-requisites for making the forecasts about future population size and structure which largely determine the health profile of a population and should underpin public health planning. Understanding the current structure of a population, and looking forward to its future, requires a review of its past. The number of very old people in a population, for example, depends on the number of births eight or nine decades earlier and risks of death at successive ages throughout the intervening period. The *proportion* of very old people depends partly on this numerator but more importantly on the denominator, the size of the population as a whole. The number of births in a population depends on current patterns of family building, and also on the number of women 'at risk' of reproduction—itself a function of past trends in fertility and mortality. Similarly, the number and causes of deaths are strongly influenced by age structure.

Demography is largely concerned with answering questions about *how* populations change and their measurement. The broader field of population studies embraces questions of *why* these changes occur, and with what consequences.

This chapter presents information on demographic methods and data sources, their application to health and population issues, information on

demographic trends and their implications, and the major theories about demographic change. The aim is to illustrate and elucidate the complex inter-relationship between population change and human health.

Global issues

Figure 6.3.1 shows that the world's population has grown rapidly since the middle of the last century and was estimated to be 7.79 billion at mid-2020 (UN 2019). While it took an estimated 123 years (from 1804 to 1927) for the world to increase its population from 1 to 2 billion, the increase from 7 to 8 billion is expected to take less than a tenth of that time (2011–22). The United Nation's medium projection suggests a further increase of some 1.9 billion between 2020 and 2050 (UN 2019). Population growth is thus expected to continue for the rest of this century, with the global population reaching just under 11 billion by the end of it. Even if there is a reasonable chance that global population growth may cease by around 2070 (Lutz et al., 2017), there will by then be nearly three times as many people as a hundred years earlier. This prospect of global population stability also masks huge differences between regions and between richer and poorer countries.

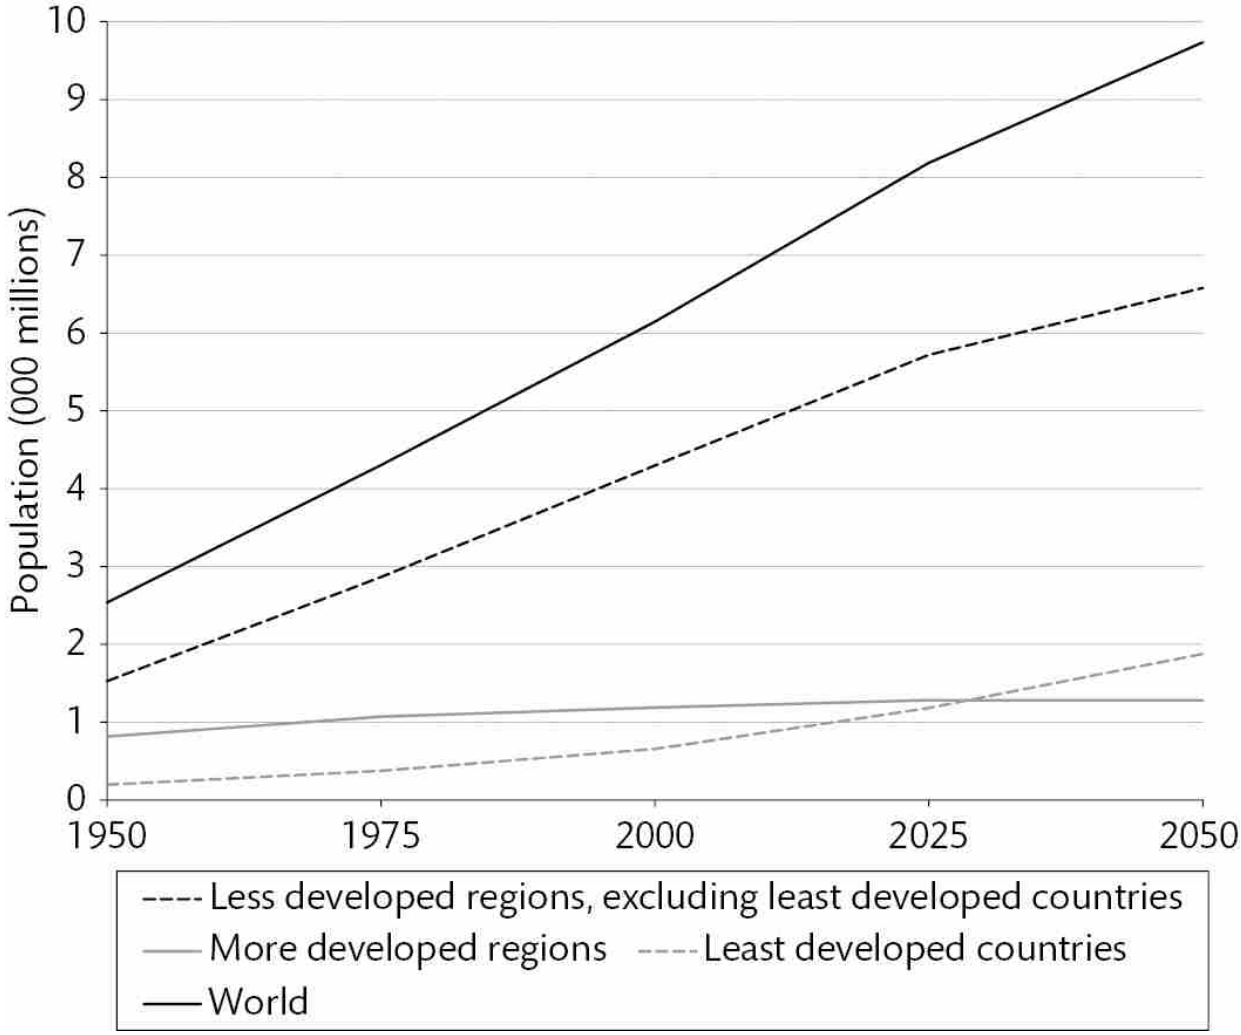

Fig. 6.3.1 Population and projected population of the world by development status.
Source: data from United Nations 2019.

Between 1950 and 2000, 77% of world population growth occurred in countries currently designated by the United Nations as less developed (excluding the least developed, see Box 6.3.1 for definitions); 13% in least developed countries and 10% in more developed regions. Between 2000 and 2050, medium term projections suggest that population growth in more developed regions will account for only 3% of the total with 63% occurring in less developed countries and 34% in the least developed. These projections imply that by 2050 the share of the world's population living in currently more developed regions will account for only 13% of total world population—compared with 32% a century earlier—while the representation

of those in the poorest countries will have increased from 8% of the total in 1950 to 20% in 2050.

Box 6.3.1 Country and regional classifications by level of development

The United Nations classifies countries into 'more' and 'less' developed and also identifies a group of 'least developed' countries. The more developed category includes all of Europe, North America, Australia, New Zealand, and Japan. The least developed countries are mostly in sub-Saharan Africa but also include Afghanistan, Bangladesh, Cambodia, and Myanmar. The classification has some anomalies in that some wealthy Asian countries are counted as less developed (e.g. Republic of Korea, Singapore, Qatar) whereas some poorer former Eastern bloc countries are treated as more developed (e.g. Albania, Belarus, Moldova), although in some more detailed schema these are identified as 'countries in transition'.

The World Bank employs a classification based on gross national income per capita which divides countries into high-, middle-, and low-income groups, with a subdivision of the middle into upper and lower. Some of the countries (principally from Eastern Europe) classified by the UN as developed fall into middle-income categories, while some of the UN less developed group are classified by the World Bank as middle-income (principally Latin American) or high income (e.g. Republic of Korea, Singapore).

Membership of the Organisation for Economic Co-operation and Development (OECD) is also sometimes used as an indicator of developed country status; members include Russia and Mexico, both of which are classified by the World Bank as middle rather than high-income countries.

The Human Development Index compiled by the United Nations Development Programme takes into account factors other than income, such as school enrolment, literacy, and levels of mortality.

Regional groupings employed by different international agencies also vary slightly.

Further details of the current classifications are available on the relevant organizations' web sites.

While some regions grapple with the needs of rapidly growing populations, such as large increases in requirements for maternal and child health services and schools, others face challenges of population ageing and, in some cases, population decline. By 2025, it is expected that over one person in five in Western Europe will be aged 65 or more and, in some countries such as Japan (where the population is already starting to decline), South Korea, Spain and Italy, projections suggest that over a third of the population will be aged 65 and over by 2050 (UN 2019). The proportions—and absolute numbers—of older people are also increasing substantially in many low- and middle-income countries, including some of the most populous such as China, India, Indonesia, and Brazil. Some low income countries with young populations will also experience very large increases in the number (but not the proportion) of older people, including the very old. For example, the number of people aged 65 and over in Kenya is expected to

increase by 460% between 2015 and 2050, compared with an increase of 70% in high-income countries. In 2015 half (53%) of the world's older old people aged 80 and over live in less developed countries, by 2050 that proportion is expected to exceed 70% (UN 2015). These variations have enormous implications for health and healthcare priorities in, and beyond, the populations concerned. Divergence in population growth between regions of the world is also fuelling mass migration, which itself has implications for global population health (Fernandes and Pereira Miguel 2009).

These hugely differing rates of growth arise from differences in vital rates and associated large variations in age structures. The global Total Fertility Rate (see Box 6.3.2 for derivation of total fertility rate (TFR)), currently about 2.5 children per woman, is half of the value in 1950 and over half the world's population now live in countries with 'below-replacement rate' fertility. In many currently developed countries the shift to lower fertility started in the late nineteenth or early twentieth centuries; what has changed in the more recent past has been fertility decline in many regions currently designated less developed and further falls in fertility in many richer countries. In a number of European countries, including Poland, Portugal and Spain, and some Asian countries, such as the Republic of Korea, Japan, Singapore, and Taiwan, women now have on average only 1.4 children or fewer, and people aged 65 and over outnumber children under 15. In sub-Saharan Africa, women on average have 4.5 children each, 40% or more of the population is aged 15 or under and only 3% aged 65 or more (UN 2019).

Many more developed countries have had below replacement level fertility since the 1970s, but their populations have nevertheless continued to grow in the past half century. The reasons why populations continue to increase in such circumstances are, firstly, that the number of births depends both on the number of women of childbearing age and how many children they each have. If the former is increasing so too may the number of births, even if women individually have fewer children each than their predecessors. In Iran, for example, the Total Fertility Rate (births per woman) declined from 6.24 in 1970–75 to 1.75 in 2010–15 but there were nevertheless more births in the latter than the former period and the population still has a high rate of natural increase (more births than deaths) (UN 2019). This reflects the large increase in the number of women of childbearing age determined by the earlier high level of fertility. One

consequence of this large built-in momentum is that it takes many decades before low fertility results in low population growth. Additionally, national population numbers may be ‘topped-up’ by in-migration, often by young adults who add to population numbers both by their own presence and because of the children they have; in many European countries about a quarter of births are to foreign-born mothers.

Levels of mortality, and associated differences in age and cause distribution of death, also vary markedly around the world. In general mortality had been declining, and the late twentieth century crises associated with the HIV/AIDs pandemic and the collapse of the Soviet Union had receded 20) before the COVID-19 pandemic emerged as a new challenge to world population health. In sub-Saharan Africa, the number of HIV/AIDS deaths in 2017, 940 thousand, was half the peak figure in 2004, although HIV/AIDS still represents a substantial and long-term public health challenge and progress towards meeting targets for reducing infections and deaths has been disrupted by the COVID-19 pandemic (UNAIDS 2020). Prior to COVID-19, there were also concerns about an apparent stalling in rates of mortality improvement in the United States and some other high-income countries attributed variously to ‘deaths of despair’ from suicide and drug and alcohol use (Case and Deaton 2015), rising obesity (Preston et al. 2018) and, in the United Kingdom, Government austerity policies (Green et al. 2017). Nevertheless, in the United States life expectancy at birth is close to 80 (and above 80 in some other high-income countries), while in some sub-Saharan countries it is below 60. Differences in the level of mortality, and in population age structure, are associated with huge variations in the distribution of deaths by age and cause. As illustration (Fig. 6.3.2), in Sierra Leone, 37% of all deaths in a year were of infants and children aged under 5, compared with 0.3% in Japan. Conversely, 68% of all deaths in Japan and 48% in Chile, a middle-income country, were of people aged 75 and over; equivalent proportions for Egypt and Sierra Leone were 30% and 8%, respectively.

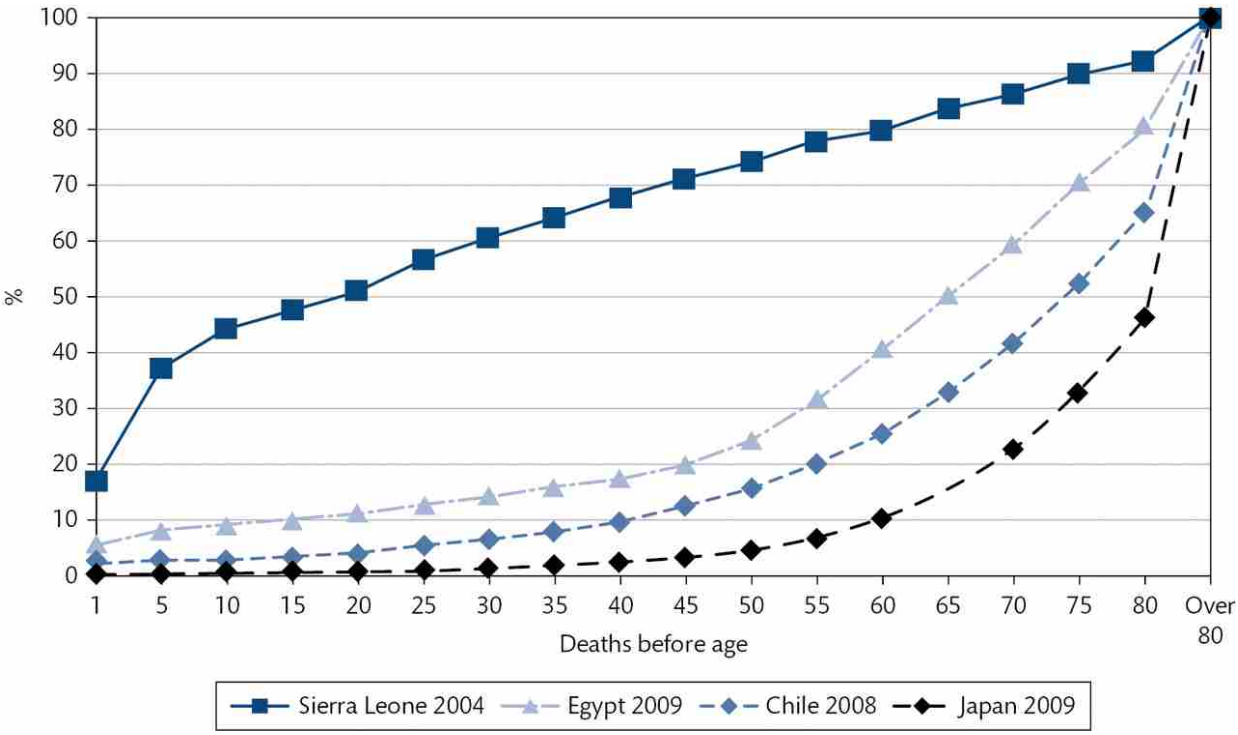

Fig. 6.3.2 Cumulative distribution of deaths by age; Sierra Leone 2004, Egypt 2009, Chile 2008, Japan 2009.

Source: data from United Nations Department of Economic and Social Affairs, Demographic Yearbook 2011, ST/ESA/STAT/SER.R/41, United Nations, New York, USA, Copyright © United Nations 2012, available from http://unstats.un.org/unsd/demographic/products/dyb/dybsets/2011.pdf.

Closely related to variations in the distribution of deaths by age are differences in the cause structure of death. In parts of the world, communicable diseases and reproductive and child health still present the most pressing public health problems. In high-income countries prior to the COVID-19 pandemic, these causes accounted for only 7% of deaths and over 70% were the result of non-communicable diseases (WHO 2018). Some countries face a ‘double burden’ with still high rates of communicable disease and poor maternal and child health but also rising rates of chronic non-communicable disease driven both by age structure changes and changes in lifestyles.

The watershed that separates populations with high fertility, relatively high mortality, young age structures and rapid growth, from those with low vital rates, older age structures, and slow or no growth, is conceptualized as the demographic transition. Identifying, and explaining, this and associated profound changes in health has been a central pre-occupation of modern demography (Lee 2003). Before turning to these issues, the basic methods

and materials of demographic analysis must be considered and the issue of population dynamics—*how* populations change—addressed.

Demographic data and methods of analysis

In the seventeenth century, John Graunt, a London merchant, used data from the London Bills of Mortality to devise an early life table, leading to him being dubbed the 'father of modern demography'. However, while Graunt had information on *numbers* of deaths, he lacked data on the population at risk and could not compute death *rates*. Essentially all demographic analysis requires data both on the population 'stock' and on 'flows' in and out—births, deaths, and migration. The traditional sources of information on the former are population censuses and, for the latter, vital registration systems.

Population censuses

The first 'modern' censuses were undertaken in Scandinavia in the eighteenth century. Censuses spread throughout Europe during the nineteenth century and most of the rest of the world in the twentieth. As well as basic questions about age, sex, marital status, and place of residence, data on other characteristics such as employment, education, and housing are often collected. The United Nations recommends that censuses be conducted at least decennially in years ending in 0 or 1.

Censuses have many strengths and are often the only source of data for small areas or population subgroups. Although primarily a tool for collecting data on population 'stock', censuses have also been used to find out about vital events. Many countries use censuses to provide data on recent internal migration (through questions on place of residence one or more years earlier) and immigration (through questions on country of birth and/or date of entry for those born elsewhere). Indirect estimation techniques developed by William Brass and others mean that questions on number of children born and number who have died, on widowhood and orphanhood, are widely used to assess mortality levels and trends using both censuses and surveys in countries with deficient vital registration systems (Preston et al. 2001).

However, censuses involve huge costs, the challenge of ensuring acceptable data quality and the problem of timeliness, as they are normally conducted only every ten years. Approaches to reducing cost (and improving quality) include use of sample censuses, either for the census as a whole, as

in China, or for more detailed questions, as in Canada; rolling censuses where parts of the population are covered each year, an approach pioneered in France, and increasing encouragement of online responses, as in the United Kingdom. Census taking requires not only a reasonable administrative infrastructure, but also the co-operation of the population to be enumerated. Some countries, including Germany and the Netherlands, have given up taking censuses because the latter is lacking and now rely on large scale surveys or 'virtual censuses' and population registration data. The twenty-first century is seeing more countries adopting alternatives as the information required by governments becomes more complex and the difficulties of mass data collection escalate. In 2010, only 11 of the 27 current EU members conducted traditional censuses (Valente 2010).

When censuses are taken, difficulties arising from errors and omissions are common, even in countries with a long history of census taking. Young, geographically mobile adults; recent (especially undocumented) immigrants; members of minority ethnic groups; infants and the very old are those most likely to be under-enumerated—some of the very groups that policy makers and health professionals may be most keen to know about.

Groups such as seasonal migrants, military personnel, people temporarily away from home and those with more than one residence also present problems. Not only are they more likely to be missed, but a decision has to be made about whether they should be assigned to their place of usual or legal residence (assuming it can be determined) or counted as belonging to the place of enumeration. The former system is termed *de jure*, the latter *de facto*. The issue of assigning people to some place of usual residence is important as often resources are allocated based on population size and characteristics. Moreover, it is essential to try and ensure that demographic events recorded in one system (vital registration) are attributed to the population actually 'at risk' of experiencing them. In richer countries, for example, most deaths occur in hospitals which may draw patients from a wide area. If these decedents are not assigned to the locality where they lived prior to hospital admission, areas including large hospitals will appear to have very high mortality rates while in others, recorded mortality will be artificially low.

Under-enumeration is usually assessed through census validation surveys (surveys of a sample of census addresses in which intensive efforts are made to contact non-respondents and check information supplied by respondents)

and comparisons with population estimates from other sources. Beyond, ensuring near-complete enumeration, the quality of the data collected is also a major concern.

In many populations, people may not always know their exact age and some approximation is reported or made by an enumerator. 'Heaping' on ages ending in 0 or 5 is a common result. Heaping can be detected by looking at the age distribution and applying various tests of consistency and such data are normally adjusted before publication. More serious problems arise when reported age is based on other characteristics, such as marital status, number of children, or grandparent status, as clearly any analysis of, for example, age at first marriage, will be biased if people's report of their age is influenced by their marital status.

Vital registration

Data on demographic events, as well as on population characteristics, are needed. In richer countries these are drawn from vital registration. Compulsory registration of births and deaths was established in most European countries during the nineteenth century. In England and Wales, for example, civil registration was introduced in 1837. Subsequent improvements to the system included those following the 1874 *Births and Deaths Registration Act* which made parents legally responsible for registering births and required attending physicians to supply information on cause of death. Other revisions have since been made, for example, the inclusion of first mother's and later father's age and in 2012, recording of all children previously borne, rather than just legitimate ones, on the confidential section of birth certificates. Most high-income countries have well-established registration systems with complete, or very near complete, coverage. In poorer parts of the world, however, vital registration systems are frequently seriously incomplete or non-existent, although there are exceptions and some countries, including India and China, have sample registration systems for selected areas. Some assessments suggest that only about a third of deaths estimated to occur globally are registered and reported to the World Health Organization, although if the sample registration systems in India and China are considered as sufficiently representative of their national populations, this proportion rises to 72% (Mathers et al. 2005, 2009). A review (Mikkelsen et al. 2015) concluded that there were modest improvements in civil registration and vital statistics

systems between 2005 and 2012 with registration of close to 40% of deaths, and 65% of births of children under 5 years.

The quality of the information supplied and coded is of course very important. No-one registers their own death and the information obtained from proxy informants may be inaccurate. Differential reporting of age, occupation, marital status, or other characteristics in the census and in other sources, such as death certificates, presents a further difficulty. Numerator-denominator discrepancies may introduce serious bias into the analysis of mortality at advanced ages, or by characteristics such as occupationally-defined social class, marital status, or ethnicity (Williams et al. 2006). The Nordic and some other European countries avoid these problems by maintaining well-developed register-based systems that link vital registration data to population, occupational, and educational registers. One study of marital status differences in mortality at older ages found marked differences in results for countries using traditional and register-based systems (Murphy et al. 2007).

Cause of death

Death certificates are the major source of information on cause of death. In richer countries, cause of death is generally certified by a physician and coded according to the International Classification of Diseases (ICD) which originated from work undertaken by the 19th century British medical statistician, William Farr. The tenth revision of the ICD came into use from 1994 and included nearly twice as many codes as ICD-9. ICD-11 was released in mid-2018 to allow member states to prepare for implementation in 2022. National preferences, as well as ICD revisions, may influence assignment of cause of death, as illustrated in a number of classic papers in which case studies of deaths were distributed to physicians in different countries. Growing awareness of particular conditions may also influence coding practices. For example, deaths attributed to Alzheimer's disease and other dementias doubled between 2000 and 2016 making this the fifth largest cause of death globally (compared to twenty-sixth in 2000) (WHO 2018). This increase reflects increases in the proportion of deaths occurring in the oldest age groups and changes associated with the introduction of ICD-10, but also effects of increased awareness and some specific

campaigns to increase recognition of these conditions (Moschetti et al. 2012).

Older people, now the vast majority of decedents in low mortality populations, are more likely to suffer multiple pathologies and the number of conditions recorded on death certificates has been increasing. Choice of one over another as the 'true' underlying cause of death is bound to be partially arbitrary. Multiple coding of death certificates and analyses by all mentions of a condition may be more informative but such data are available in only a few countries (Anderson 2011). Variations in death certificate coding reflecting differences in medical knowledge and diagnosis; in the extent to which autopsies are used; in classification systems and the quality of registration systems are a major factor complicating analyses of trends over time or between countries.

Deaths assigned to symptoms, signs, and ill-defined conditions such as 'old age' or 'senility' or other causes lacking diagnostic meaning, sometimes referred to as 'garbage codes', present a particular problem. Mathers et al. (2005) in an investigation of coverage and quality of cause of death coding in 2003, found that in some countries over 40% of deaths were assigned to these 'causes'. Only 23 countries met their definition of high quality of data with coverage of at least 90% and fewer than 10% of deaths assigned to ill-defined codes.

Variations in coding practices and use of ill-defined codes complicate comparisons over time, as well as between countries. In a classic text, Preston (1976) argued that there was an inverse association between the proportions of deaths assigned to circulatory diseases and to ill-defined causes, and that part of the apparent twentieth century epidemic in heart disease mortality in richer countries may have been an artefactual consequence of improvements in death certification. In England and Wales, for example, 41% of deaths of people aged 80 and over in 1911–15 were assigned to ill-defined causes compared with only 4% a century later.

In countries which lack adequate certification and registration systems, data on deaths by cause are seriously limited. Attempts have been made to develop verbal autopsies, protocols for collecting information from lay informants which can be reviewed by physicians and used to assign cause of death (Wang et al. 2007, 2012). This approach has been useful in a number of small investigations and is being employed on a larger scale, for example in India (Gajalakshmi and Peto 2004). However, one study which tested

physician-certified verbal autopsies in six sites in four poorer countries against gold standard assessment found a concordance of less than 50%, with substantial variability by cause and physician (Lozano et al. 2011). The development of extensive test data sets with which to make comparisons of verbal autopsy findings and calibration against computer algorithms, rather than physician assessments, is an expanding area of enquiry with some promising results (Murray et al. 2011). In the absence of routinely recorded data, estimates may be obtained by modelling. The most ambitious exercise is the Global Burden of Disease programme which has used a large array of sources and methods, including expert knowledge, vital registration, field surveys, surveillance and police and mortuary data to derive estimates of cause-specific mortality by age and sex for 235 separate causes for every country in the world (GBD 2016).

Other data sources

Many countries have a range of surveys which collect more detailed information on, for example, health-related behaviours, family-building strategies, or reasons for migration that would be impossible to collect in a census. In poorer countries, where other data sources are scarcer, surveys often present the best source of information on basic demographic parameters. Data quality is potentially better in a survey than a census, as it is more likely that well-trained interviewers can be used. The World Fertility Survey (WFS), an international population research programme launched in 1972 to determine fertility levels throughout the world, and its successor, the Demographic and Health Survey Programme (DHS), have been particularly valuable in providing demographic and health data for a range of poorer countries. Other approaches include multiround surveys, in which respondents are asked about events since last contact, and dual-record systems which involve two independent data collection systems (one often a multiround survey), the results of which are then combined. This method allows some estimation of missed events but is expensive. These approaches are described in more detail in most demographic textbooks (Preston et al. 2001; Rowland 2003; Siegel and Swanson 2004).

The raw materials of demography relate to individuals' most personal experiences—sexual activity, family formation, birth control, reproduction, marital breakdown, illness, and disability. All of these occur in a social framework which attaches value to some of these behaviours and stigmatizes

others. Not surprisingly, respondents in censuses and surveys may be reluctant to disclose non-marital pregnancies, illegal abortions, undocumented migration, or deaths of relatives from HIV/AIDS. Concealment has also been the policy of some national governments which have treated demographic data as official secrets. Additionally, the enormous potential complications arising from people's uncertainties about age or other 'basic' characteristics; uncertain recollections of prior events and the vast scope for administrative errors have to be considered. The demographer's traditional obsession with data quality is hence understandable. Differences in perceptions and reporting of health status are also problematic and have bedevilled attempts to make international comparisons of health status as, even if questions are harmonized, the ways people respond to them are not (Ritu et al. 2002). Increasingly health-related surveys collect information on observer measured indicators, including biomarkers, as well as self-reported information on health and functioning which allows this issue to be addressed, although raising other problems related to intraindividual variability, observer variation, and differences in laboratory practices.

The statistics produced in data sets produced by the UN, WHO, Organisation for Economic Co-operation and Development (OECD), and other national and international bodies series have their origins in what is or has been *done* by millions of people, mediated by what is *said* about these events and experiences, further filtered by how this is *recorded*, processed, and analysed. Some assessment of data quality is generally given but sometimes users may pay insufficient attention to this.

The analysis of demographic data

A standard array of techniques and measures forms the basis of much demographic analysis; the most common of these are described briefly next. Further detail is supplied in a number of textbooks (Preston et al. 2001; Rowland 2003; Siegel and Swanson 2004). Analysis involves not just the application of a particular technique, but decisions about what units of analysis to use and how to group them. A major distinction is between *period* and *cohort* analysis. Period analysis deals with events of a particular time period (for example, mortality rates 2010–2015) while cohort analyses follow the experience of individuals through time. Cohorts in this sense are

defined as groups of people who have experienced the same significant event at the same time. Thus, birth cohorts comprise people born in a particular year or group of years and marriage cohorts those marrying at a particular time. Cohort and life course approaches to analysing mortality and other indicators of population health have an intuitive appeal and are increasingly used, both fuelling and fuelled by a growing number of longitudinal studies. Cohort analysis of time series data may be used in the absence of specially collected longitudinal data.

Cohort and period are two of the dimensions which 'place' persons in time; the third is age. Duration effects (such as duration of marriage, proximity to death, or length of exposure to a particular pathogen) may also be important. Cohort effects may be substantial and, unless allowed for, may mask relationships between age and various risks. Differences in the smoking behaviour of cohorts, for example, have a major effect on the relationships between age and smoking-related disease observed at different periods (Preston and Wang 2006).

Decisions about whether to use individuals, families, households, or geographic areas as units of analysis are often constrained by data availability. Until relatively recently, most census data were only available as aggregate tabulations, but individual-level information is increasingly available. Other innovations include the development of samples including linked census, vital registration and in some cases health service data such as the longitudinal studies available for countries of the United Kingdom and a number of others (Young et al. 2010). In these data sets, individuals' census records are linked with their vital registration records so numerator-denominator biases in, for example, the analysis of mortality are avoided. In Nordic and some other countries, the whole population has been assigned personal identification numbers facilitating linkage of information from a range of registers. Linkage to use of health and care services is also available in some countries, such as Finland.

These advances have greatly extended the material available for analyses of variations in demographic behaviour, and their consequences. They have also raised complex security and confidentiality issues fuelling debate over appropriate restrictions on access to data.

The measurement of fertility

Fertility means the childbearing performance of a woman, couple, or population. Generally, only live births are included. The term fecundity, by contrast, is used to refer to the physiological capability of producing a live-born child. A rough idea of fertility may be gained from using census or survey data to calculate child-woman ratios: the ratio of 0–4 year olds to women aged 15–49. However the survival of infants (and their mothers) and the age structure of the female population affects these ratios, so they are generally only used if no other data are available.

The simplest measure of fertility commonly used is the crude birth rate—the number of births in a particular year per 1,000 population. As the denominator of this includes those not 'at risk' of giving birth (women outside reproductive age groups and men), it is really a ratio rather than a rate. Crude birth rates are influenced by the age structure of the population, but less seriously so than crude death rates. In 2010–15 crude birth rates ranged from less than 10 per 1,000 in parts of Europe to nearly 50 per 1,000 in the highest fertility countries of sub-Saharan Africa (UN 2019).

Slightly more informative is the general fertility ratio—births per 1,000 women of reproductive age (generally defined as 15–49 or 15–44). Where data allow, age-specific fertility rates (births per 1,000 women of a particular age or age group) are preferred. These are frequently summarized using the TFR. Where, as is usually the case, period data are used to calculate this, it indicates how many children women in a hypothetical cohort would have if they experienced current age-specific fertility rates throughout their reproductive life. This measure is sometimes explicitly denoted TPFR (total period fertility rate). In low mortality populations, a TFR of 2.1 is taken to indicate *replacement level* fertility as, under this regime, a cohort of women would be succeeded by a cohort of daughters of the same size (after some allowance for mortality and the fact that 105–106 boys are born for every 100 girls).

One limitation of the TFR is that it is affected by changes in the 'tempo' rather than the 'quantum' of childbearing. If women start delaying their fertility but 'catch up' later, there will be a divergence between cohort and period measures, as the latter will be based partly on the behaviour of earlier cohorts whose timing of births was different. Similarly, if women have children earlier, TFRs will rise, even if eventual family sizes remain unchanged. This means that period measures are much more volatile than

cohort ones. For these reasons, many statistical offices use cohort, rather than period, measures of fertility as the basis for projections.

More sophisticated measures of fertility include parity progression ratios. These indicate the probability of proceeding from one birth to another (for example, what proportion of mothers with two children progress to having a third). Parity progression ratios are normally calculated for cohorts who have completed, or nearly completed, their childbearing but it is also possible to use data on births by birth order to derive period progression ratios (Bongaarts and Feeney 1998).

In the past, demographers often preferred to calculate age-specific *marital* fertility rates (and TFRs and other measures) on the grounds that the unmarried population is not 'at risk' (or at reduced risk) of childbearing. Changes in marital fertility indicative of deliberate attempts to limit family size are regarded as one of the defining features of the fertility 'transition' (see next) and so distinguishing these from changes due to variations in the 'at risk' (married population) has been particularly emphasized. However, rises in non-marital childbearing, which now account for over 40% of births in OECD countries and over 60% in France, mean that restricting analyses to marital fertility is generally no longer appropriate.

Reproduction rates

In the absence of migration and with fixed mortality, populations will grow if mothers replace themselves with more than one (surviving) daughter and decline if they have fewer than one. Theoretically, it would also be possible to measure the replacement of fathers by sons, but in practice the difficulties involved in obtaining paternity data make this infeasible. Reproduction rates thus relate only to female fertility—births of daughters. The gross reproduction rate (GRR) is derived in the same way as the TFR except that age-specific birth rates based only on births of daughters are used in the calculation. The net reproduction rate (NRR) makes an allowance for mortality; specifically, the chance that a daughter will herself survive to childbearing age. The NRR cannot be calculated unless both age-specific fertility and mortality data are available (although it can be approximated using the GRR and appropriate life table survival data). Changes in either fertility or mortality (or both) will mean a divergence between period

measures (based on the experience of a hypothetical cohort) and the experiences of real cohorts.

Summary information on measures of fertility and reproduction is shown in Boxes 6.3.2 and 6.3.3.

Box 6.3.2 Fertility measures

Definitions:

Fertility: the childbearing performance of individuals, couples, or populations.
Fecundity: the physiological capability of producing a live birth.
Parity: the number of children previously born alive (or sometimes number of previous confinements) to a woman or couple. Nulliparous women are those who have borne no children.

Measures:

Crude birth rate: The ratio of births in a year (other specified period) to the average population in the same year/period (mid-year population), expressed per 1,000:

$$\text{CBR} = \frac{\text{number of births}}{\text{mid-year population}} \times 1{,}000.$$

General fertility rate: births to women aged 15–44/49 in a year/period per 1,000 women aged 15–44/49 in the same period:

$$\text{GFR} = \frac{\text{number of births to women aged 15–44/49}}{\text{mid-year population of women aged 15–44/49}} \times 1{,}000.$$

Age-specific fertility rate (ASFR): number of births to women aged x (or x to x + n) per 1,000 women aged × (or × to × + n). 'n' refers to the length of an age interval.

ASFRs are frequently calculated for five year age groups from 15–19 to 40–44 or 45–49:

$$\text{ASFR} = \frac{\text{births to women aged x}}{\text{mid-year population of women aged x}} \times 1{,}000.$$

Total (period) fertility rate (TFR/TPFR): the sum of the age-specific fertility rates for all reproductive age groups for a particular period (usually a year), conventionally expressed per woman. The TFR indicates how many children a woman would have if throughout her reproductive life, she had children at the age-specific rates prevalent in the specified year or period.

x = 49:

$$TFR = \sum_{x=15}^{x=49} f_x$$

where 'f_x' is the age-specific fertility rate at age x. If rates for age groups, rather than single years, are used then the sum of the age-specific rates must be multiplied by the number of single ages included in the group (usually five).

x = 45–49:

$$TFR = 5 \sum_{x=15}^{x=45-} f_x$$

x = 15–19.

Parity progression ratio: the probability of a women of parity x progressing to parity x + 1.

Box 6.3.3 Reproduction ratios

Measures:

Gross reproduction rate (GRR): The sum of the age-specific female fertility rates (births of daughters), for all reproductive age groups for a particular period (usually a year) conventionally expressed per woman. The GRR indicates how many *daughters* a woman would have if, throughout her reproductive life, she had children at the age-specific rates prevalent in the specified year of period. The GRR can be calculated either by summing female age-specific fertility rates (relating to births of daughters rather than all births) or using the formula:

$$GRR = TFR \times \text{Proportion of female births}$$

The proportion of female births can be taken as 0.488 (100/205) in the absence of more detailed information.

Net reproduction rate (NRR): the average number of daughters that would be borne, according to specified rates of mortality and of bearing daughters, by a woman subject through life to these rates. The NRR employs the same fertility data as the GRR, but also takes into account the effects of mortality. An NRR of 1.0 indicates that a population's fertility and mortality levels would result in exact replacement of mothers by daughters.

The measurement of mortality

As for fertility, the simplest measure of mortality is the crude mortality rate, deaths per 1,000 population. This is strongly influenced by age structure. For example, although life expectancy at birth in high-income countries in 2015–

20 is estimated to be some 18 years longer than in low income countries (81 years and 63 years, respectively), the crude death rate—deaths per 1,000 population of all ages—was *higher* in the high-income country group (8.8 compared with 8.1 in low income countries) (UN 2019). This apparent paradox reflects the fact that the proportions of older people with higher risks of death are much greater in high-income countries. Age (and sex) specific rates, or measures based on them (such as life expectancy at birth), are therefore much to be preferred if data are available to calculate them. Both direct and indirect standardization are sometimes used to make comparisons between populations with different age and sex structures. Standardized mortality ratios (SMRs) are calculated using indirect standardization. This involves selecting a set of 'standard' age-(and often sex) specific mortality rates, for example those for a national population, and applying these to the numbers of people in the relevant age groups in the subpopulation of interest—for example, the population of a particular region. This yields an 'expected' number of deaths—the number of deaths there would be in the subpopulation if age-specific death rates were the same as those in the standard population. The ratio of observed to expected deaths gives the SMR. Thus an SMR of 1.24 indicates that mortality in the subpopulation is 24% higher than in the standard population, after allowing for age differences. SMRs are useful summary measures of differences in mortality but give no indication of the *level* of mortality. In direct standardization the adjustment is carried out the other way and a set population structure is used to weight mortality data to produce age-standardized rates. EUROSTAT, for example, produces a European standard population to facilitate comparisons across populations. Comparisons are of course only valid if the same standard population is used.

Age-specific death rates are calculated using the numbers of deaths at age x (or between ages x and x + n) in a particular year as the numerator and the mid-year population of the same age as the denominator. The rate is conventionally expressed per 1,000 or per 100,000 population. The mid-year population is used as a measure of the average population at risk on the assumption that deaths are evenly distributed throughout the year. For some age groups, notably infants, this assumption is invalid. In low mortality populations, deaths in the first 3 days of life may account for half or more of all deaths in the first year of life. Moreover, information on the size of population aged less than 1 year normally comes from birth data (as in 9 out

of 10 years relevant census data will not be available). For these reasons live births in a particular year are conventionally used as the denominator of the infant mortality rate while deaths to infants aged less than 1 constitute the numerator. Some infants dying in a given year will have been born in the previous year and some born in the year in question will die the following year. This can cause distortions if there are large annual fluctuations in numbers of births (or infant deaths) and often three-year averages are preferred. Deaths at very old ages are also not evenly distributed throughout the year and an adjustment is often made to allow for this.

Infant mortality rates (IMRs) were very high in some parts of historical Europe—with 300 or even 400 deaths per 1,000 live births in regions of Russia and Germany at the end of the nineteenth century (van de Walle 1986). In England and Wales at the start of the twentieth century, there were some 140 infant deaths per 1,000 live births. Infant mortality in high-income countries is now extremely low—fewer than two infant deaths per 1,000 live births in some European countries. There have also been huge falls in infant mortality in many poorer countries; in China infant mortality fell from 42 deaths per 1,000 births in 1990 to 7 in 2019. In India the equivalent fall was from 88 to 28. However, rates remain high in some of the very poorest countries—up to 8 deaths per 1,000 live births (WHO 2017).

Variations on this scale have substantial demographic impacts. Infant mortality has also attracted particular interest because of links with fertility behaviour and as an indicator of public health conditions. Particularly in this latter context, perinatal, early, and late neonatal and post-neonatal mortality rates are often distinguished where data allow (see Box 6.3.4).

Box 6.3.4 Mortality measures

Crude death rate: The ratio of deaths in a year (other specified period) to average population in the same year/period (mid-year population), expressed per 1,000:

$$\text{CDR} = \frac{\text{number of deaths}}{\text{mid-year population}} \times 1{,}000$$

Age-specific mortality rate (ASMR): number of deaths to persons aged x (or x to x + n) per 1,000 persons aged x (or to x + n):

$$\text{ASMR} = \frac{\text{deaths to persons aged x}}{\text{mid-year population of persons aged x}} \times 1{,}000$$

Standardized mortality ratio (SMR): the ratio of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

$$\text{Infant mortality rate IMR} = \frac{\text{deaths to infants aged} < 1 \text{ year in year x}}{\text{number of live births in year x}} \times 1{,}000.$$

sometimes decomposed into *neonatal mortality rates* (deaths of live-born infants during the first 4 weeks) and *post-neonatal* mortality (from 4 to 52 weeks)

The **perinatal mortality rate** measures late foetal deaths (stillbirths) and early neonatal deaths relative to live births.

$$\text{Perinatal mortality rate} = \frac{\text{still births + deaths under 1 week}}{\text{still + live births}} \times 1{,}000.$$

Still births used to refer to deaths of foetuses of 28 or more weeks' gestation, however an earlier threshold of 24 weeks is now more generally used.

Life tables

Life table analysis is a core demographic technique and life tables provide one of the most powerful tools for analysing mortality and other demographic processes. Life tables show the probability of dying (and surviving) between specified ages. They also allow the calculation of various other indicators, including expectation of life. If complete data on the mortality of a birth cohort are available, then a cohort life table may be constructed. However, the use of cohort life tables is obviously only possible retrospectively. More commonly, period life tables, based on mortality rates at a particular time, are calculated. These life tables show death (and survival) probabilities for a hypothetical cohort with an arbitrary radix (number of babies at the beginning) usually set to 10,000, 100,000, or some other multiple of 100.

Specific notation, summarized in Box 6.3.5, is used in life table analysis. The basis of the table is a set of probabilities of dying—$_nq_x$—which are calculated from age-specific death rates. x here refers to age at the start of an interval whose length is specified by n. Thus $_5q_{50}$ refers to the probability of someone alive at 50 dying between age 50 and age 55. The complement of

${}_nq_x$—the probability of surviving—is denoted ${}_np_x$. The (hypothetical) number of survivors at each age is given by l_x; thus l_o equals the radix (of 100,000) and l_{75} the number of survivors at age 75. The number of person years lived in an interval (${}_nL_x$) and the total number of person years lived after a particular age (T_x) are often not shown in published tables but are steps on the way to the calculation of e_x—life expectancy at age x.

Box 6.3.5 Life table measures and notation

x = age attained last birthday
l_0 = the radix of the life table (hypothetical number of babies), usually 100,000
l_x = number of survivors at age x, so l_{65} is the number of persons alive at age 65 in the hypothetical life table population
${}_nq_x$ = probability of dying between age x and x + n, so ${}_4q_1$ is the probability of dying between age 1 and 5 for a person aged 1
${}_np_x$ = probability of surviving between ages x and x + n, so ${}_{20}p_{65}$ is the probability of surviving from age 65 to age 85 for a person aged 65
${}_nd_x$ = number of deaths between age x and x + n
${}_nL_x$ = number of person years lived between age x and x + n
T_x = total number of person years lived after age x
e_x = expectation of life at age x, so e_0 is expectation of life at birth

This measure provides an indicator of mortality which is very largely independent of the age structure of the population since it depends only on age-specific mortality rates. This makes it more useful than either an SMR (which gives no indication of level and, like directly standardized rates, depends on the choice of standard) or a crude death rate (which is strongly influenced by age structure). Life expectancy either at birth (e_0) or further life expectancy at a particular age, say 65 (e_{65}), is calculated by dividing the total person years lived after age 0 or 65 (T_0 or T_{65}) by the number of survivors aged 0 (l_0) or 65 (l_{65}).

Values of life expectancy at birth are sometimes (mis)interpreted as indicators of usual age at death in a particular population. In very low mortality populations where most deaths occur within a relatively small range of ages (see the example of Japan in Fig. 6.3.2), there will be a close

correspondence between median and modal ages of death and life expectancy at birth (which is a mean value). However, in populations such as Sierra Leone where many deaths occur in infancy, there will be a wide divergence. There is also sometimes confusion about the interpretation of values of further life expectancy at a particular age. This is derived from information about the probabilities of death and survival at *subsequent* ages, and so is not influenced by deaths at earlier ages and it is erroneous to think that, for example, the further life expectancy of someone aged 65 will equal life expectancy at birth minus 65. The higher are mortality rates at young ages the greater will be this divergence. For example, in the United States in 1900–01—when mortality rates among infants and children were high—women aged 65 had a further life expectancy of 12 years, even though female life expectancy at birth was only 49 years. In 2016 there was a much closer correspondence between female life expectancy at birth (81 years) and female further life expectancy at age 65 (21 years).

Model life tables

Patterns of age-specific death rates show similarities whatever the level of mortality. Death rates tend to be higher in infancy than later childhood and rise with age from around the age of puberty, although in the oldest age groups rates of increase tend to flatten out. Because of the tendency for death rates at one age to be associated with death rates at other ages in a given population, it is possible to derive hypothetical schedules, called *model life tables*, describing variations in mortality by age and sex, normally in terms of a limited number of parameters which allow for particular features of the mortality pattern of the population considered. Model life tables are derived from empirical data from countries where these are available. They are extremely useful aids for the estimation of mortality by age in populations with defective data. They are also used (in conjunction with fertility data) to show the outcomes of particular fertility and mortality regimes on, for example, population age structure and for making population projections. All demographic texts give further details of their derivation and application.

Other applications of life table analysis

Life tables are widely used to analyse probabilities associated with events other than death, such as risks of divorce or contraceptive use failure and discontinuation rates, and in estimates of disability-free or healthy life expectancy. Many chronic conditions associated with ageing, such as musculoskeletal and sensory impairments, may have serious implications for health status but are not directly life-threatening. Life table methods are used to decompose total life expectancy into 'healthy' and 'unhealthy' or 'disability-free' and 'disabled' components. This can be done using cross-sectional data on morbidity or disability prevalence in conjunction with mortality data, although this has some limitations. More sophisticated (and data demanding) multistate approaches and simulation methods which allow for transitions both to and from disabled states have also been developed (Manton et al. 2006; Wolf and Gill 2009). Despite these technical advances, there is still controversy about *trends* in health and disability, particularly in older age groups. To a large extent this debate arises from measurement problems and the difficulties involved in making comparisons between health indicators derived in different ways, a further reminder of the importance of data quality and measurement.

Multiple decrement life tables allow 'decrements' from more than one event—for example different causes of death. Cause elimination life tables are also used to identify the 'pure' severity of a particular cause of death, although strong assumptions are required. Multistate models allow analysis of a range of transitions, particularly those where re-entries into a particular state, such as being married or living in a certain region, are possible. These more sophisticated applications of course require more detailed data.

The measurement of migration

In 2018, 55% of the world's population lived in urban areas compared with 29% in 1950 (UN 2018). This huge shift, which has important public health implications, has been largely driven by rural to urban migration, especially in Asia and Latin America. Measuring migration represents particular difficulties. The classical definition of internal migration is a permanent or semi-permanent move across an administrative boundary, which means that the extent of migration recorded depends partly on the size of administrative areas. For example, in a country divided into many small areas, a move over 10 kilometres will count as migration, which would not be the case for

countries divided into larger ones. Hence, international comparison of internal migration rates is potentially misleading. Even the distinction between international and internal migration may be problematic if boundaries are unrecognized, contested, or changing. The temporal dimension to migration presents further difficulties; what constitutes permanent or semi-permanent and how should groups such as seasonal migrants be treated?

The reason for defining migration as a move over a boundary is largely pragmatic. Often only moves of this kind are recorded; moreover this is the information required by local administrations. Some countries have registration systems in which changes of address are recorded. More commonly, censuses are used to find out about migration. Questions on usual address one or five years ago allow the proportion of *movers i*n the population to be measured (except for those aged less than one or five). These data also allow inflows *and* outflows between pairs of areas to be measured. *Moves,* as opposed to *movers,* are not directly measured as someone moving several times in the reference period cannot be distinguished from someone moving only once. Those leaving an address and later returning to it cannot be identified either. This means that the length of the reference period used is important; the proportion of movers in the five years preceding a census will *not* equal five times the proportion moving in one year before the same census.

In the absence of direct census data, estimates of migration can be made indirectly using the ‘balancing equation’ referred to next. Differences in the size of a population at two points in time not accounted for by natural change (i.e. births minus deaths) must be due to migration (or data errors). If vital registration data are available, then both births and deaths can be taken into account. If they are lacking, then the survival of groups enumerated in the first of a pair of censuses must be estimated from a life table and the number of expected survivors compared with the number enumerated in the second census (obviously ageing must be allowed for, so the number of 20–29 year olds in the first census will be compared with 30–39 year olds 10 years later). These methods only allow estimation of *net* migration (balance between in-migration and out-migration). Their major weakness lies in the fact that the residual population balance assumed to be due to migration may in fact reflect differences in the quality of the two censuses considered or errors in the estimates of survival used.

Survey data are also used to measure migration and potentially provide illuminating information on the reasons for, and consequences of, migration. However, as migration over long distances is a relatively rare event, even large general population samples may yield relatively few migrants. A similar problem besets samples of international travellers, such as the UK International Passenger Survey, designed to estimate flows of international migrants through port or border surveys. Tourists and business travellers comprise the vast bulk of people entering or leaving so surveys are an inefficient way of identifying immigrants and emigrants. Compiling advance passenger information electronically, and logging both entries and exits, presents a possible alternative method of capturing movements, although one that presents various legal and practical problems. The UK e-borders initiative, for example, was judged some 10 years after its inception to have met some targets, but not the one of improving estimates of in- and out-migration (Vine 2013). Moreover this, and similar initiatives, are designed to gather information on people travelling on a recognized route who are prepared, or compelled, to provide information to secure passage or entry. It is thus of little use as a method for measuring movements of refugees and asylum seekers pursuing other transit modes.

Unfortunately, other data are often lacking as legal and administrative record systems are frequently concerned with citizenship and right of abode rather than international migration *per se* (and virtually never with emigration). Estimates of the size of immigrant populations depend on whether the measure used is based on place of birth or on nationality—the size of the latter is influenced by policies on acquisition of citizenship.

Population dynamics

Any population comprises those who have made an entry and not yet exited. When whole populations of defined geographic areas are considered, the only means of entry are birth or immigration and the only means of exit death or emigration.

The most basic method of demographic analysis is the decomposition of overall population change (P_t—P_0) into its components (B, D, I, E):

$$P_t - P_0 = B - D + I - E$$

where P_t = population at an end of period; P_0 = population at the beginning of a period; and B, D, I, E represent respectively births, deaths, immigrations and emigrations during the same period (B-D is referred to as natural increase and I—E as net migration). Population subgroups may be similarly defined in terms of entries and exits. In the absence of migration, entry to the population aged 75 to 84 is through ageing (passage from 74 to 75) exit is through further ageing (84 to 85) or death. This simple accounting equation is an important one, both methodologically and as a formal reminder of the need to consider *past* as well as current events.

Of the three demographic determinants of population size, structure, and growth, fertility has historically been of much greater importance than either mortality or migration. Every birth represents not just an addition to the current generation of children, but also potentially an exponentially increasing augmentation in the size of future generations. Death carries no such promise of future return. Births increase the population only at age zero, so making it younger, whereas deaths are spread across the whole age range and so have much less impact on age structure. The third determinant —migration—is generally not of significant magnitude to have a major impact on most national populations, although there are exceptions especially when natural increase is close to zero and a few populations, such as some of the Gulf states, are heavily dependent on migrant labour. Increased levels of immigration to many European countries since the 1990s have had an effect on population size and age structure in some. The population of Spain for example, increased by 10.2% between 1999 and 2006 and over 90% of this increase was due to migration (Sobotka 2008). It is also anticipated that the importance of migration as a driver of population change will increase in the next few decades as a result of lower fertility in developed regions (UN 2017).

For social and biological reasons fertility, mortality, and migration have interactive effects. Decreases in mortality among women with reproductive potential, for example, influence not just the size of the age group affected at the time, but also the size of succeeding generations. Declines in male mortality, particularly in populations where large age differences between spouses are common and remarriage of widows is rare, will similarly tend to increase fertility by effectively increasing the proportion of women of reproductive age who are still married. Conversely, reductions in fertility clearly reduce the risk of maternal mortality and in low income settings may

have further beneficial effects on the survival of mothers, infants, or both. Age at motherhood also influences rates of population growth. The average age of mothers at the birth of their daughters is termed the mean length of a generation and is generally around 29 years. A shorter interval will mean more rapid generational succession (and faster population growth).

Migration affects other demographic parameters because migrants differ from the general population. International migrants are generally young and in good health and often move from relatively high- to low-fertility populations. Consequently, immigrants may serve to (temporarily) 'rejuvenate' the host population and, at least initially, often have higher fertility and lower mortality. In England and Wales, for example, in 2011 the TFR for foreign-born women was 2.2. compared with 1.8 for the UK born (Office for National Statistics 2017). Despite the disadvantages they may face, mortality of immigrant groups is often lower than that of host populations because of the differential selection of immigrants—the healthy immigrant effect (Kennedy et al. 2015). The degree of selection tends to vary according to difficulties and distance to be overcome in making an international move. For all these reasons, the demographic characteristics of population subgroups largely comprising immigrants and their immediate descendants may vary substantially from those of the population as a whole.

Population projections

Population projections represent one of the most widely used outputs of demographic analysis. Strictly speaking a projection simply represents the outcome of applying various assumptions about future fertility, mortality, and migration and so differs from a *forecast*, which implies prediction. However, projections are often treated as forecasts and the degree of uncertainty inherent in them is not always sufficiently recognized, although the production of probabilistic forecasts in recent UN projections, makes this more explicit. The most common method of projection is the component method, based on the balancing equation ($P_t = P_0 + B—D + I—E$). Assumptions are made about the three components of change—births, deaths, and migration—and applied to age and sex groups within the initial population to give a projection of future size and structure. To a large extent, assumptions are based on recent trends together with other information, for example, survey data on fertility intentions or (sometimes) models of change in particular causes of death. Forecasting fertility has generally been

regarded as the most problematic area of projection but recently greater attention has been paid to the errors that have been made in forecasting mortality in developed countries. This has little effect on age groups in which survival is high but can have quite substantial impacts on forecasts of the number of older people. Migration may be an important element and may be underestimated, if projections do not take into account feedback loops whereby migrant populations tend to generate further migration (Bongaarts and Bulatao 2000). International migration is also difficult to project as it is affected by events outside the country, is often a sensitive political issue and may be volatile. Partly for these reasons, immigration levels have been consistently underprojected in forecasts in many European countries (Alders et al. 2007).

Population growth

Changes in the size of a population produced by the surplus (or deficit) of births over deaths are termed natural increase (or decrease). A common indicator of growth is the crude rate of natural increase—the difference between the crude birth rate (annual births per 1,000 population) and the crude death rate (annual deaths per 1,000 population). If net migration is zero, this will be the same as the growth rate of the population—the overall annual change in the population divided by the population size—(conventionally expressed as a percentage). In Europe as a whole and Japan, deaths outnumbered births in 2015–20. In other countries, births still outnumber deaths even though fertility rates have been below the level required for *long-term* replacement for 50 years or so. As already noted, this apparent paradox largely reflects the fact that the number of births is a function of the number of potential mothers, to which immigration may also contribute, as well as of their fertility patterns. If the former is increasing so too may the numbers of births, even if women have fewer children each.

The young age structures of many populations in the developing world mean that these populations have a huge built-in potential for growth. Population *momentum* is the measure which gives the ratio of the ultimate size a given population would achieve to current population size if fertility were to immediately fall to replacement level. The population of Africa is projected to increase from 1.2 billion to 2.5 billion between 2015 and 2050 (UN 2019), a consequence of both population momentum and high levels of fertility. In some low fertility countries there are now concerns about

‘negative momentum’—the prospect of decline in population even if fertility rates increase somewhat because of successively smaller cohorts of women in childbearing age groups.

Intrinsic rate of natural increase: stable population theory

Early in the twentieth century Lotka (1907) demonstrated mathematically that a population closed to migration and subject to unchanging age-specific fertility and mortality rates for a long period would eventually have a fixed age structure (in which the proportion in each age group remained unchanged) and would grow at a constant rate. This type of population is called a *stable* population. The fixed age structure of a stable population is independent of the initial age structure—two very different populations subject to the same unchanging rates for a long period would eventually assume the same structure. A particular case of a stable population is a *stationary* population—one in which birth and death rates are constant and in balance and so population growth is zero. The L_x column of the life table is an example of a stationary population. The number of births is fixed (the radix) and the age distribution is also fixed. In non-stationary stable populations, the age structure is also fixed but the size of every age group is growing at the same constant rate as the overall population and the number of births. This is called the *intrinsic rate of natural increase* and is a function of the NRR and the mean length of a generation (approximated by the mean age of childbearing).

Although stable and stationary populations are theoretical constructs, real populations at various times have met the model requirements closely enough to allow stable population theory to be used to develop methods for indirectly estimating fertility and mortality in populations lacking adequate directly derived data. Stable population models are also widely used for insurance, pension, and personnel planning. One of the important results of the work of Lotka and his successors was to show theoretically the important influence of fertility on age structure during the demographic transition.

Age structure

Population pyramids graphically illustrate the current structure of populations and in so doing, also provide insights into both the future and

the past of the population. High fertility populations have a pyramid shape with each successive cohort being larger than its predecessor. The population pyramid for Bangladesh (Fig. 6.3.3a) shows a typical pattern for a population with a history of high fertility but a recent downturn. Each successive cohort is larger than the preceding one, with the exception of the youngest. 'Old' populations, such as that of the United Kingdom (Fig. 6.3.3b), are more rectangular with a gradual tapering at the top. Bulges in population pyramids due to high numbers of births have 'echo' effects when members of large cohorts themselves have children. Thus the baby boom experienced in many populations in the post-Second World War period (precise timing varied between countries) had an echo effect in the1980s.

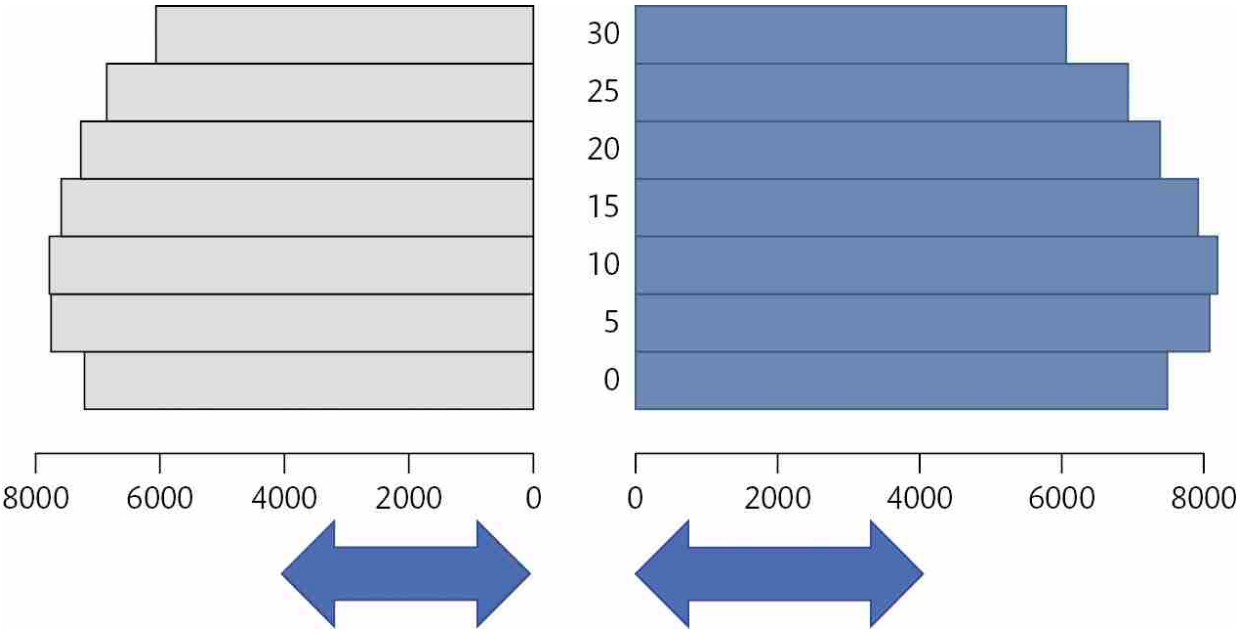

Fig. 6.3.3 Distribution of the population of (a) Bangladesh and (b) the United Kingdom by age and sex, 2010.

Source: data from United Nations, World Population Prospects: The 2010 Revision, United Nations, New York, USA, Copyright © 2012, available from http://esa.un.org/wpp/documentation/pdf/WPP2010_Volume-I_Comprehensive-Tables.pdf.

Historically, and apparently paradoxically, improvements in mortality in those European populations which now have high proportions of old people in fact served to *offset* the trend towards population ageing, as they chiefly benefited the young—and led to increases in the proportions surviving to

have children themselves. However, although fertility has the greatest *potential i*mpact on age structure and population growth, in some circumstances mortality (or migration) may become a more important influence. Many populations in richer countries now have had fertility at or below replacement level for an extended period, life expectancies at birth close to 80 and near universal survival to the end of the (female) reproductive span. In these conditions, further improvements in mortality have the greatest impact at old ages and further population ageing occurs from the apex, rather than, or in addition to, the base of the population pyramid. Mortality changes are now the main motor of the further ageing of a number of populations with already old age structures (Preston and Stokes 2012). Population age structures and associated rates of growth or decline, changes in age structures such as population ageing, and the speed and stage of age structural change all have important economic and health implications which have attracted considerable debate and controversy.

Many economists have pointed out that population growth has often provided a spur to human ingenuity and economic growth. Less positively, the countries which now have the youngest age structures and most rapid rates of population growth are already suffering from land degradation and in many cases, constrained agricultural potential (Alexandratos 2005). Large and growing child populations also hamper efforts at improving human capital through education or improved health (Casterline 2010). Many women in poorer countries, particularly in sub-Saharan Africa, still have unmet needs for family planning with consequent potential negative impacts on their own health and that of their children (Cleland et al. 2014).

Reduced fertility initially produces a ‘demographic dividend’ or ‘window’ when the ratio of children to adults falls and those in prime productive ages, the survivors of larger birth cohorts, account for a higher proportion of the population. It has been argued that this dividend of lower child dependency and higher representation of adults in the prime working age groups played an important part in the rapid economic development of the ‘East Asian Tigers’, like South Korea and also China (Bloom et al. 2000). The next phase, involving high and increasing representation of older people may, it has been suggested, also bring some economic benefit in the form of increased savings (by the large number of older people) and so greater capital available for investment even though gross domestic product (GDP) and national income growth are likely to slow down (Lee and Mason 2017).

The major concerns arising from increases in the proportions of older people relate to effects on productivity and increased need and cost for support systems of various kinds, including pensions, healthcare, and long-term care. In OECD countries, healthcare expenditure is typically three to five times as high for those aged 65 and over as for those aged under 65. However, there is considerable international variation in the proportion of GDP devoted to healthcare spending for older people which bears little obvious relationship to the proportion of older people in the population concerned. (Rechel et al. 2013). Even in rich countries much of the support needed by older people with disabilities is provided by family members, and in many poorer countries families are also important providers of economic support. Population ageing thus has implications for intergenerational transfers at both the population and the family level. Adaptation of policies, including public health initiatives to promote healthy ageing and encouragement of increased economic activity at older ages provide a means of addressing some of these concerns (Rechel et al. 2013; Bloom et al. 2015; WHO 2015).

Some countries have also responded with explicit policy changes designed to increase fertility. The Republic of Korea modified its population policy in 2006 and introduced a range of ‘family friendly’ measures designed to increase fertility; in 2012 Iran shifted from promoting ‘two children are enough’ to ‘at least two children are ideal’, accompanied by large cuts in family planning budgets, and China moved from a ‘one child’ to a ‘two child’ policy in 2015.

In populations which have more recently moved to low fertility and low mortality regimes, the pace of demographic change has been much faster than occurred historically in Europe. The proportion of the Japanese population aged 65 and over doubled, from 7% to over 14%, between 1970 and 1996. In France a similar increase took 130 years to achieve and in Sweden 85 (Kinsella and Phillips 2005). In countries such as China, Thailand, and Brazil an equivalent shift has occurred, or will occur, in around 30 years (UN 2015). More recently ageing populations have thus had a much shorter period in which to adapt to new public health priorities. The origins of these age structure changes lie in the demographic transition.

The demographic transition

Towards the end of the nineteenth century (earlier in France) birth and death rates started falling in a number of European countries. Between 1871–75 and 1911–15 the TFR for England and Wales, for example, dropped from 4.8 to 2.8; by the early 1930s it was below replacement level, a development which was viewed with alarm and led to the first Royal Commission on Population. Although modern methods of contraception were lacking, it was clear that this huge drop in fertility was the result of the deliberate limitation of family size. Half of couples married in the 1870s had six or more children compared with 12% of couples married in 1911–15 (Coleman and Salt 1992). Expectation of life at birth, meanwhile, increased by some 15 years between the end of the nineteenth century and the early 1930s.

Researchers attempting to relate such shifts in demographic regimes to economic and social changes, originated the theory of the demographic transition. The 'classical' view propounded by Notestein (1945) and others was that in 'traditional' societies fertility and mortality are both high and roughly in balance. Change is driven by economic advance which results in lower mortality. Fertility initially remains high, resulting in a rapid period of population growth. After this lag, however, fertility also falls in response to falling mortality and the erosion of 'traditional' pro-natalist values.

This classical view has since been considerably modified (Lee 2003; Bongaarts 2010). Coale and his collaborators in an ambitious project to track the transition in historical Europe suggested that no economic 'threshold' for fertility decline could be identified and that the pattern of decline seemed to follow regional groupings, suggesting a cultural rather than a socioeconomic dimension (Coale and Watkins 1986). Caldwell et al. (1992, 2007) additionally argued that in non-European countries, it was not so much socioeconomic modernization but 'Westernization' involving increased emphasis on the nuclear family and a change in intergenerational wealth flows (resulting in the costs of children outweighing their potential benefits) that was the important trigger of fertility transition.

Research on the historical demographic transition in Europe may seem of limited relevance to contemporary problems. However, this research was fuelled by post-war fears about population growth. By 1950, significant mortality declines had been achieved or initiated throughout the world. In China, for example, expectation of life at birth increased from 43 in 1960 to over 75 by 2010. In this context it seemed imperative to discover the causes of fertility decline and use this knowledge to accelerate fertility 'adjustment'

to falling mortality. Was ‘development the best contraceptive’ as concluded at the stormy 1974 World Population Conference; could change be achieved through intensive family planning programmes, as the experience in Taiwan and South Korea seemed to suggest; or was some combination of these and other factors the key to fertility transition? Studies of societies in which the fertility transition had occurred seemed to offer the best prospect of an answer to these questions. While simple answers to complex questions are rarely forthcoming, Coale (1973) identified three factors which he considered pre-requisites for fertility decline in contemporary populations. These were: that potential parents must think it acceptable to balance the advantages and disadvantages of another child; that some advantage must be gained from reduced fertility and that effective techniques of fertility control must be available. This paradigm, subsequently elaborated into the idea of ‘Ready, Willing and Able’ (to deliberately control fertility), has dominated research on fertility motivations and behaviours ever since (Lesthaeghe and Vanderhoeft 2001).

Trends in fertility in the second half of the last century and early part of this have shown considerable divergence and shed some light on these debates. TFRs are highest in sub-Saharan Africa; with Niger, Democratic Republic of the Congo, Somalia, and Mali, having TFRs above, close to, or above 6 in 2015–20 (UN 2019). In all other world regions there was clear evidence of onset of a transition to lower fertility by the 1970s or 1980s; Japan was the first non-Western country to experience a fertility transition starting after the Second World War. Subsequently, substantial fertility declines have occurred in a number of countries which at that time had only a limited amount of development, such as Sri Lanka, Thailand, China, and more recently Bangladesh. As already noted, one of the largest and fastest recent fertility declines took place in the Islamic Republic of Iran (Abbasi-Shavazi et al. 2009) defying assumptions that socially and religiously conservative Muslim societies with low rates of female employment would be resistant to fertility change.

Recent interpretations of fertility change have reverted to considering development—in its broadest sense rather than restricted to consideration of average incomes—a stronger influence in contemporary populations than ideational changes, although the relevance and role of cultural and policy related factors is recognized (Bryant 2007). Common factors identified in poor rural populations where fertility has fallen significantly are well-

established education systems, improvements in healthcare and in child survival, some form of extrafamilial welfare, well-organized local government, and an organized family planning programme. Potential benefits of investing more resources in fewer children, as a consequence of increasing opportunities in urban or industrial livelihoods, also seem to be important (McNicoll 2006; Bryant 2007). The education of women has been identified as a particularly significant influence on both falling fertility and improved infant survival—and better health throughout the life course (Samir and Lutz 2017).

As noted earlier, fertility rates remain high in much of sub-Saharan Africa. Continuing expressed preferences for large families and other family and social characteristics of African populations have led some to conclude that the model of change seen in Asia and Latin America may not be applicable to Africa, or at least not to all regions of Africa (Caldwell et al. 1992; Caldwell 2007). There is nevertheless evidence of unmet demand for family planning and a strong case can be made, on the grounds of improving maternal and child health, for renewed investment in family programmes which in some places faltered as the policy focus and funding shifted to the HIV/AIDs crisis (Cleland et al. 2014).

Recent trends have also made it clear that the endpoint of fertility transition is not necessarily a fertility level around the ‘replacement rate’. In some countries, such as Guatemala, Peru, Egypt, Turkey, and Ghana, fertility declines ‘stalled’ (sometimes temporarily) at a level higher than two children per woman (Bongaarts 2010). In others they have continued downward, spiralling a new set of concerns about ‘lowest low’ fertility.

The second demographic transition

In contrast to the scenario of high fertility and rapid population growth in some of the poorest countries, a growing number of high-income countries now have concerns about the implications of low fertility. Many of these countries experienced a post-Second World War ‘baby boom’ during the 1950s and early 1960s followed by a 1970s ‘baby bust’ when fertility declined to very low levels. In Scandinavia, France, the United Kingdom, the United States, and other English-speaking countries fertility rates have since fluctuated at levels between 1.6 and replacement level with something of an increase in the first decade of this century—a pattern also seen in many

other industrialized countries. These populations have also experienced a range of family related behavioural changes, included marked increases in cohabitation, non-marital childbearing, divorce, postponed childbearing, and increased levels of childlessness, described by some as a 'Second Demographic Transition' (Lesthaeghe and Niedert 2006). Such behaviours, which have become more usual among Northern European cohorts (and a number of countries outside Europe) born from around the 1950s onwards, are much less prominent in Southern and Eastern Europe and the richer countries of South and East Asia. However, it is mainly in these latter countries that 'lowest low' fertility—rates below 1.3– has been prevalent with 21 countries from these regions having TFRs below 1.3 in 2003. The recent increase in fertility in developed societies meant that only three of these countries, South Korea, Slovakia, and Singapore, had average values below 1.3 in the period 2010–15 (Goldstein et al. 2009; UN 2019). However, the TFR remained below 1.5 in a large number of other countries including Italy, Japan, Poland, Spain, and Ukraine.

An important determinant of very low fertility in many of these societies has been a precipitous fall in marriage rates (Billari and Kohler 2004). Japan, for example, has been transformed from a society with near universal marriage in the early and mid-twentieth century to one in which a fifth of the population will remain never-married at age 45 (Retherford et al. 2001). In this case the erosion of arranged marriages after the Second World War has played a part; changing gender roles may also be important.

The proximate determinants of fertility

One of the contributions of research into the fertility transition has been improved understanding of biosocial influences on reproduction. A huge range of social, economic, cultural, and psychological factors may influence decisions about family building strategies and family size. However, these can only have effect if they are translated into patterns of behaviour or physiological characteristics that influence the risks of conception or delivery.

Conversely, other patterns of behaviour with potentially important influences on fertility may be adopted with little or no thought to these consequences. In a classic paper, Davis and Blake (1956) distinguished a series of 'intermediate fertility variables'; factors influencing exposure to

risk of pregnancy (marriage and coital frequency); risk of pregnancy (such as use of contraception) and pregnancy outcome (spontaneous and induced abortion). The most influential refinement of this work is the Bongaarts decomposition model (Bongaarts 1978), which identified four elements chiefly responsible for observed fertility variations:

the proportion of women married (exposed to risk);
contraceptive use;
induced abortion;
post-partum non-susceptibility to conception (largely determined by breastfeeding practice).

The TFR is dependent on the interactive effect of these variables and hypothetical maximum fertility. In modern 'post-transition' populations, fertility decisions are normally couple- (or woman-) based and are implemented through contraception and abortion. In non-contracepting populations, biosocial factors, notably marriage patterns, breastfeeding practices, sexual frequency and, in some populations, the prevalence of infertility, are of major importance.

The social reproductive span, from entry to end of marriage or any sexual union, nearly always comes later, often much later, than menarche. Fecundity—the potential for bearing children—decreases after the third decade, more sharply after the age of 35 and in most non-contracepting populations the average age at last birth is around 40. Social factors, as well as biological ones, are important influences. Sexual activity may cease before menopause because of widowhood or separation and in some populations, childbearing after becoming a grandmother is disapproved of. In some Western countries fertility rates after age 40 have recently risen, after a long period in which they were falling, reflecting an increase in the postponement of motherhood in order to avoid clashes with educational and career advancement. For some women this may be facilitated by the availability of medically assisted reproduction. In England and Wales, for example, in 2017 fertility rates for women aged 40 and over were slightly higher than for teenage women (ONS 2018).

For those within the effective reproductive span—biologically capable of childbearing and in a sexual union—overall fertility in non-contracepting populations is largely a function of the length of intervals between births. This is determined to a considerable extent by breastfeeding patterns as the

duration of post-partum amenorrhea is much longer for mothers with protracted periods of intensive breastfeeding. Longer birth intervals and increased breastfeeding also have positive effects on infant and child health. Overall deaths before the age of 5 might be reduced by as much as 30% in some countries if closely spaced births were delayed (Cleland et al. 2014).

The epidemiological transition

Transitions from relatively high to low mortality regimes have in all populations been associated with transformations in the age, cause, and sex structure of death. Omran (1971) coined the phrase ‘epidemiological transition’ to describe this process. Changes in the response of societies to health and disease processes also need consideration. The term ‘health transition’ has been proposed as one which embraces both these phenomena.

Substantial falls in death rates from infectious and parasitic diseases and maternal mortality are hallmarks of the epidemiological transition. In England and Wales, over half the gain in life expectancy at birth between 1871 and 1911 was due to reduced infectious disease mortality. Some 20% of the total gain was due to reduced death rates from tuberculosis (Caselli 1991). Declines in these causes of death were greater among the young, the epidemiological transition has also been consistently associated with larger falls in mortality among women than men. Changes in the intrahousehold allocation of resources, declines in causes of death primarily affecting women (such as maternal mortality and respiratory tuberculosis), gender differences in health-related behaviour and in exposure to occupational hazards, and the possibly greater susceptibility of men to stresses associated with socioeconomic changes, may all be underlying factors.

The relative contribution of various eighteenth and nineteenth century developments in promoting the historical epidemiological transition in the West remains a matter of debate. Improved nutrition, better housing and living conditions, public sanitation schemes, and specific public health initiatives, such as smallpox inoculation all have their adherents. In the early twentieth century, improved personal hygiene practices and better infant care were also important. A common thread linking most of these factors is their relationship to overall social and economic development and improvements in standards of living. During the twentieth century, however, developments in medical technology and vector control offered the potential for

'exogenous' mortality decline less dependent on a particular country's level of income and development. One consequence was that the relationship between *per capita* income and life expectancy has shifted to the right (Preston 2007). In 1901, for example, life expectancy in the United States was 49 and income *per capita* was about US$7,300 (2005 purchasing power parity). In 2009 income *per capita* in China was almost identical ($7,400) but life expectancy was 73 years (http://www.gapminder.org/).

Many poor countries have been able to achieve remarkable falls in mortality, especially child mortality, through behavioural change, improved education of women, and introduction of relatively cheap treatments and interventions, such as vaccination and antibiotics (Cutler et al. 2006; WHO 2013). Between 1975–80 and 2010–15, life expectancy at birth increased from 52 to 71 in Bangladesh and from 58 to 69 in Indonesia (UN 2019) and there are now a number of poor or middle-income countries with life expectancies at birth as high as in the United States.

The process of the epidemiological transition (or at least the initial phases) is now complete or underway in much of the world and non-communicable causes of death predominate in all regions, except sub-Saharan Africa.

Recent demographic trends and public health

Population size, growth and age structure are all outcomes of variations in demographic behaviours and all have implications for population health and well-being. Population ageing will almost certainly be the predominant demographic issue of the twenty-first century in nearly all richer and a growing number of poorer countries. The strong association between age and risks of health impairment and disability imply growing needs for support services, even if levels of disability fall. In those countries which are growing old before they grow rich, changes in family support systems for older people may pose additional challenges. A range of strategies for responding to these challenges have been proposed including encouraging longer working lives through review of retirement and pensions policies, better organization of acute and long-term care services and initiatives to promote healthy ageing (Rechel et al. 2013; WHO 2015).

Changes in marriage and family patterns also have other public health implications. In North America and North West Europe (and also Latin America and the Caribbean) high rates of divorce and non-marital

childbearing mean that increasing proportions of children are spending at least part of their childhood in lone parent families. Although causal pathways are difficult to elucidate because of various selection effects, there is evidence indicating poorer health among lone mothers and their children, and among unmarried (especially divorced) people more generally, so these trends have some negative implications. Moreover, in the United States and a number of other populations there are indications of a widening socioeconomic (and ethnic) divergence in family patterns (Cherlin et al. 2016) which may contribute to, or compound, the increases in health disparities observed in many populations.

Continuing improvement in child and adult mortality is projected for the poorer world. In the poorest countries the interaction of rapid population growth, environmental degradation and conflict pose continuing health problems and some demographers have argued that population growth has already reached the point at which disastrous environmental and economic implications are inevitable (Dyson 2010). In other middle and low income countries, patterns of tobacco use are likely to have a substantial effect on health trends in coming decades (West 2006). Rapid increases in childhood obesity pose another challenge (Wang and Lobstein 2006).

Issues such as international migration, economic and cultural globalization, and climate change all have substantial health implications for the rest of the twenty-first century; all interact with demographic patterns and processes. Measuring these trends and assessing their effect on health and demand for healthcare requires an understanding of population dynamics and population-based measures, and suitable demographic data. Demography is thus an essential component of public health.

6.4

Health promotion, health education, and the public's health

Fran Baum

Introduction

Health promotion is a complex, ambiguous concept and set of practices. While many have linked it, primarily, to a revolution in health education, its roots go much deeper into the history of public health. It had its contemporary beginnings in the throes of the backlash against bureaucratic and professional dominance exemplified by the new social movements of the 1970s and 1980s. At its heart, health promotion is centred on the values and principles of equity, participation, and empowerment. These concepts are embedded in health promotion's founding document, the Ottawa Charter for Health Promotion. However, exactly how these values are articulated is often ambiguous. In this chapter, the authors contend that health promoters must intensify their reflection on these core values and principles; particularly in the light of the tendency to slip back into a comfortable paternalism, which reinforces existing power imbalances. We are specifically concerned with the precise interpretation of health equity in health promotion. In order to pursue a deeper level of reflection on the meaning of equity, it is argued that health promotion must engage more deeply with recent developments in political philosophy, political economy, and social theory. Following up from the work of the World Health Organization (WHO) Commission on the Social Determinants of Health, one of health promotion's emerging priorities is a reinvigorated push for the global development of 'healthy public policy' as seen in the Health in All Policies (HiAP) movement. This chapter, also addresses the need for health promotion to engage more directly with core social-theoretical concepts related to the generation of social inequalities that underlie health

inequities; finally, we explore the relevance of complexity science and systems thinking for health promotion research.

Health promotion, health equity, and action on the determinants of health: an introduction

Previous attempts (Green and Raeburn 1988; Tones and Tilford 1994; Tones 2002) to situate health promotion within the broad field of public health have often used ‘health education’ as the starting point. This is an entirely sensible approach which we will discuss but it tends to underemphasize the *radical* departure health promotion aims to make from traditional public health approaches in general. Without claiming health promotion means everything all at once, thereby leaving its lofty rhetoric in the realm of the aspirational yet ineffectual, we aim to place health promotion more centrally in the ongoing saga of an increasingly globally aware public health. As one of the acknowledged founders and innovators of the modern health promotion movement has unceasingly argued, health promotion, at its most persistent and radical, heralds a ‘new public health’, not merely a more fine-tuned and effective tool-box for a less paternalistic health education (Kickbusch 1989, 2007).

We will begin with a clear definition of health promotion. Then, by unpacking the dense and sometimes opaque wording that define the elements of health promotion as a concept, we intend to open up some of its central, yet often hidden, connections to much broader themes in contemporary social and political movements and ideas.

Next, we situate health education and its internal critique as an important part of the history of health promotion, while providing more context concerning the specific historical/national trajectories that made the genesis of the modern health promotion movement a mixture of different influences, of which health education is only one.

We will consider how health promotion manages its ambiguous relationship with the history and ideological background of public health, and how it sees itself in relation to the past, present, and future of public health.

We suggest there is a new opportunity for health promotion to reconnect with the avant-garde in public health, which can be examined along two

broad dimensions, namely how to achieve health equity, and the question of health in a global political-economic context. Particular attention will be paid to the recent work following up the WHO Commission on the Social Determinants of Health, led by Sir Michael Marmot, and the renewal of the *Ottawa Charter* action area of 'healthy public policy' in the *Health in All Policies* global movement, spearheaded by the WHO.

In this chapter we argue that there is insufficient engagement with social theory within the health promotion field. We offer some suggestions and map out potential pathways towards more serious reflection on this missing social-theoretical base. Finally, we consider the emerging role of complexity theory and systems thinking in health promotion research.

In general, this chapter on health promotion is *critical* in the positive sense of the word. Previous surveys of the concept and practice of health promotion that provide excellent guidance to the field are referenced. However, we consider that practitioners and researchers in public health can benefit from a reflexive inquiry into the rich ambiguities and tensions that are embedded in the discourse and practice of health promotion. This is particularly the case if, as we argue, the development of health promotion *is* the development of a 'new public health' (Baum 2016).

'Health promotion': a definition and conceptual critique

In this chapter, we will follow the *Ottawa Charter for Health Promotion* (WHO 1986) definition of health promotion as 'the process of enabling people to increase control over, and to improve their health'. However, we will also draw upon the expanded definition in the updated *Health Promotion Glossary*:

> Health promotion represents a comprehensive social and political process, it not only embraces actions directed at strengthening the skills and capabilities of individuals, but also action directed towards changing social, environmental and economic conditions so as to alleviate their impact on public and individual health. Health promotion is the process of enabling people to increase control over *the determinants of health* and thereby improve their health. (WHO 1998, our emphasis)

Here, the 'how' and 'why' *ideology* is linked to the 'what' of the *determinants of health* (WHO 1998). This is crucial, because if health promotion is about anything, it is about *action* taken across the broad

spectrum of health determinants, particularly directed towards the social, environmental, and economic conditions that support health (WHO 1984).

The *Glossary* also emphasizes that 'participation is essential to sustain health promotion action', and identifies the three *Ottawa Charter* strategies for health promotion: '*Advocacy* for health to create the essential conditions for health indicated above; *enabling* all people to achieve their full health potential; and *mediating* between the different interests in society in the pursuit of health.'

These strategies are supported by five priority action areas as outlined in the *Ottawa Charter*:

Build healthy public policy
Create supportive environments for health
Strengthen community action for health
Develop personal skills, and
Re-orient health services (WHO 1986)

As one can see from these definitions, we already have started the 'unpacking'. A more nuanced analysis of some of the key elements in this definition is described in the following subsections: the 'process' of health promotion; 'enabling' and 'empowering'; and for what, the outcome, 'improved health'. This will be followed by an analysis of the *Ottawa Charter strategies* and its *priority action areas* (often called 'action strategies').

As soon as we begin, we find ourselves in murky waters, though not without some guidance. Ironically, although health promotion is, as Tones and Green (2004) noted, an 'essentially contested concept', there has been a remarkable degree of effort, and consensus, concerning its ostensive definition. Few, if any, health promoters dispute the *Ottawa Charter*'s now canonical phrasing (WHO 2005).

The real ambiguity that surrounds the concept of health promotion is embedded in the elision of the concrete meaning of the elements that make up its agreed upon definition.

Health promotion as a process

The emphasis on *process* is important, if only because it warns against reducing health promotion to merely a technical function of public health. It connotes the wider meaning of the concept by signalling that the radical departure and critique of traditional public health lies in its advocacy for changing the *way* we do public health, just as much as *what* we change and *why* we change.

Health promotion, whether it be generated from an internal critique of health education or from other dissatisfactions with the way public health was being practised, is fundamentally concerned with change and, specifically, with the failure of traditional, paternalistic, and professionally dominated public health processes to bring about positive changes in health, particularly for those groups that suffer disproportionately negative health outcomes and the consequent disadvantages. What is substituted is a call for health promoters to create a dynamic, participatory engagement with individuals and communities, to help or 'enable' them to take control over the determinants of their own health.

The first ambiguity we meet when trying to analyse this 'process' turns on whether one interprets the health promotion process as, primarily: a revamped tool-box of health education techniques and social marketing devices, with a rhetorically efficient participatory gloss; or, as a values-based process of communicative interaction that has as its central premise the ethical foundation of respect for human dignity and autonomy. These are certainly polar extremes and there is no doubt that there is room for both aspects in a broad, ecumenical attitude to a diverse field of practical action. Yet, because health promotion is a process often dominated by professionals, in a context where its supposed beneficiaries are often those in a position of relative powerlessness, the tendency for professionals to retreat to an insulated cocoon of technical expertise is strong. The essence of the health promotion process is a focused shift of power from professionals to the community and to individuals within their communities who historically have had less power. To do this, it is crucial that the 'process' we focus on is the one that involves negotiating values, principles, ethics, and power, not the less complicated one of transferring a packet of new skills and technical tools to a community that is presumed to lack capacity. In order to achieve this shift in power, health promoters need to begin by examining their own values and assumptions that inform their actions.

Beliefs and assumptions underlying health promotion

Health promotion practice is influenced by the beliefs and assumptions we hold. While a detailed discussion of this topic is beyond the scope of this chapter, we outline how certain beliefs and assumptions influence how we act in health promoting ways in given situations.

Beliefs are learned through life experiences; they are what we hold as 'true'. They are convictions that influence the way we think, feel, and act. Health promotion practice relies on a set of underlying assumptions that guide those who work in the field. Hartrick et al. (1994) contend health promotion is a 'way of being' that requires certain convictions in order to act in health promoting ways. These include:

All people have strengths and are capable of determining their own needs, finding their own answers, and solving their own problems.
Every person and family lives within a social-historical context that helps shape their identity and social relationships.
Diversity is positively valued.
People without power have as much capacity as the powerful to assess their own needs (people are their own experts).
Relationships between people and groups need to be organized to provide an equal balance of power (this includes professional/client relationships).
The power of defining health problems and needs belongs to those experiencing the problem.
The people disadvantaged by the way that society is currently structured must play the primary role in developing the strategies by which they gain increased control over valued resources.
Empowerment is not something that occurs purely from within (only I can empower myself), nor is it something that can be done to others (we need to empower the group). Rather, empowerment describes our intentional efforts to create more equitable relationships where there is greater equality in resources, status, and authority.
Shared power relations do not deny health professionals their specialized expertise and skills. Rather, professional expertise and skills are used in new ways that result in greater power equity in interpersonal and social relations (Hartrick et al. 1994, p. 87).

So, for example, if we consider the first assumption in the list, believing that people are able to find their own answers and solve their own problems leads one to act in empowering ways because of the belief that people have this capacity to figure things out. On the other hand, if one believes that people need to be told what to do, or that they are not able to figure out issues on their own, it is more difficult to create conditions that are enabling. For some, it might even feel irresponsible to put people in these circumstances or to allow them to have control over these types of decisions.

Enabling and empowerment

At the time of the *Ottawa Charter*, the word ‘enabling’ was favoured, although later this tended to be replaced with the more direct and comprehensive concept of ‘empowerment’. Essentially, this meant that a prerequisite for the new approach was that individuals and communities were to directly participate in the planning and implementation of health promotion activities. The assumption was based on the notion that only by genuinely participating in the health promotion process would people be ‘enabled’ or ‘empowered’ to take control of what determined their health. However, the concept of ‘enabling’ also referred to the more general process of changing the social, economic, and environmental conditions that made it difficult for people to become empowered. There is a deep ambiguity here: it is not clear, for some commentators, whether more macro-scale action, at a policy level, also requires active participation of local communities. There is some room for an interpretation that tends to retain a traditional paternalism when it comes to healthy public policy, leaving the ‘participatory’ aspect of health promotion to the realm of ‘community action’. As will be argued throughout this chapter, health promotion is constantly at risk of sliding back into this paternalistic approach, leaving the more ‘complex’ and high-level ‘technical’ decisions to the experts. Yet, if there is a direct link between human dignity, autonomy, and equity, then *all* aspects of health promotion must integrate the fundamental perspective of participation. In fact, it is argued that the rhetoric of ‘empowerment’ often masks a continuing bureaucratic and

professional dominance of the process of improving public health (Baum 2007).

A key aspect of this ambiguity can be seen when we consider the link to health inequity. Without a genuinely participatory, empowering process, it is those worst off who are left further behind as they suffer, not only a failure to affect those conditions most important to their health, but also a direct assault on their human dignity (Sennett 2003). Those who tend to manage any gains from processes that lack true participation are usually segments of the population that already have access to positions of status and the resources and capacities to take advantage of the interventions on offer. The distinction here is between a situation where already disadvantaged people are assumed to be too ignorant or incapable of participating and thus have solutions imposed on them, and a situation where people of a privileged status delegate, as equals, to professional experts. This is not to say that a participatory process is not better for everyone, regardless of class position or status; rather, it is to emphasize that non-participatory processes have a disproportionate adverse effect on disadvantaged groups.

On the positive side, an empowering health promotion process leaves the ownership and control of a health promotion activity or programme in the hands of the community itself. This is particularly important in communities that have suffered historical social injustices and have thus been actively ‘disempowered’ (an ugly but accurate term). Allowing people to participate in a genuine way in determining not only *what* they want but *how* they want to get it is demonstrably the most effective strategy for change. It is also the *only* strategy for sustaining progress in improving health and shifting control back to the community and away from a negative dependence on bureaucratic and professional power. In this model, professionals are not demons; they are just transformed from arrogant experts into supportive servants of the will of the community.

There is in these simple terms (‘enable’ or ‘empower’) the entire, complex, and ambiguous story of health promotion. All the themes that will be touched upon in this chapter can be traced back to just what is at stake in the ostensive goal of ‘empowering’ people to take control over what determines their health.

What is the ‘health’ in health promotion?

Understanding how we conceptualize health is a key reflective step in health promotion. How we think about health largely determines the types of action we take to promote health. We see next how different historical conceptions of health still shape the contemporary health landscape and continue to sustain ambiguities in how people approach health promotion itself. In the twentieth century, due to the relative success of the sanitation approach to public health and the emergent hegemony of the germ theory of disease, an implicit biomedical definition of health as *the absence of disease* dominated, and along with it, a narrow, individual treatment focus, centred on the healthcare system, was the preferred solution. The WHO had, in 1946, introduced the *positive* definition of health as ‘a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity’ (WHO 1946). Nevertheless, this definition had little concrete impact on actual health systems, leaving the absence of disease approach to health as the default option when governments turned their attention to the public’s health.

The Lalonde Report, an official document produced by the Canadian Department of Health and Welfare (Lalonde 1974), marked a significant change in thinking about health. Although the report is recognized internationally as the first government document to suggest that health promotion could be a key strategy for improving health, its other, more significant contribution, was to redefine how we view health. Lalonde’s report argued that the healthcare system plays only a small part in determining health, and suggested that health was determined by the interplay between human biology, healthcare organization, environment, and lifestyle. This view of health became known as the ‘lifestyle or behavioural approach to health’, partly because the ‘environmental’ dimension was either ignored or treated narrowly.

With the publication of the discussion paper on concepts and principles of health promotion (WHO 1984) and the endorsement of the *Ottawa Charter for Health Promotion* (1986), a third view of health arose: the socioecological approach. This approach defined health as ‘a resource for everyday life, not the objective of living’. ‘Health is a positive concept emphasizing social and personal resources as well as physical capacities’ (1986, p. 1). In order to reach this state of physical, mental, and social well-

being, people must be able to identify and realize their aspirations, to satisfy their needs and to change, or cope, with their environment. This inextricable link between people and their environment provides the conceptual basis for this socioecological perspective on health and it forms the conceptual base for health promotion practice.

At first glance, these different views of health may appear to be developmental or historical. However, Labonté and others (Labonté 1993; Rootman and Raeburn 1994; Raeburn and Rootman 2007) argue that, in fact, all three views of health (along with many other definitions) continue to be endorsed by different people in the field of health promotion and, furthermore, that the view of health one holds influences one's health promotion practice. Table 6.4.1 illustrates this connection between how we think about health, our view of health, and our actions (health promotion practice). For example, if we hold a view that health is the absence of disease, we are likely to talk about disease processes and risk factors and to manage the problem professionally by prescribing a treatment. If we hold a socioecological view of health, we are more likely to focus on the conditions in which the person is living, the factors that are influencing their ability to meet their needs, and to use enabling strategies to assist the person to have more control over their health.

Table 6.4.1 From concept to action: different approaches to health

	Medical approach	Behavioural approach	Socioecological approach
Health concept	Biomedical; absence of disease or disability	Individualized; physical-functional ability, physical well-being	Positive state connectedness; ability to do things that are important or have meaning; psychological well-being
Health determinant	Disease categories, physiological risk factors (e.g. hypertension)	Behavioural risk factors (e.g. unsafe sex)	Psychological risk factors (e.g. isolation) and socioenvironmental risk conditions (e.g. poverty)
Principal strategy	Surgery, drugs, therapy, illness care, medically managed behavioural change	Advocacy for healthy lifestyle choices	Personal empowerment, small group development, community organization, coalition advocacy, political action
Programme development	Professionally managed	Negotiated with communities and professionals	Managed by community in critical dialogue with supporting professionals and agencies

The *Ottawa Charter* strategies

The three strategies mentioned in the *Ottawa Charter* are: *to advocate*, *to enable*, and *to mediate*. We have already reflected upon the second strategy, as it is part of the definition of health promotion. However, a few words need to be said about the other two strategies.

The concept of *advocacy* receives very little elaboration in the *Ottawa Charter*. In the *Health Promotion Glossary*, it is stated that advocacy 'can take many forms including the use of the mass media and multimedia, direct political lobbying, and community mobilization through, for example, coalitions of interest around defined issues. Health professionals have a major responsibility to act as advocates for health at all levels in society' (WHO 1998, p. 6). This raises one of the many thorny issues that come up when professionals are caught between highly mobilized and often highly critical communities and a state bureaucracy that is extremely reticent about providing funding that sanctions and supports the capacity for critical attention to its policies and programmes. Even at the level of

independent professional organizations, the participation and funding provided by government bodies creates a tension around the organization taking strong critical perspectives. Another aspect of this strategy, as defined in the *Glossary* and glossed over, is the potential contradiction between activities such as 'political lobbying' and 'community mobilization'. Often, the same organization or individual will be less effective as a political lobbyist to the extent they are perceived to be directly associated with community mobilization efforts that the powerful are either indifferent to, or actively disfavour.

Mediation is an even more delicate strategy for health professionals. Its original *Glossary* definition in relation to health promotion was: 'A process through which the different interests (personal, social, economic) of individuals and communities and different sectors (public and private) are reconciled in ways that promote and protect health' (WHO 1986). In the expanded definition of 1998, more explicit emphasis is given to the potential conflicts that often arise between the competing interests mentioned in the original definition. However, the goal of mediation as 'reconciliation' is left unchanged. While there is nothing inherently wrong with the idea of reconciliation, professionals should be extremely self-critical and reflexive when operating with this strategy. Two dangers are apparent with the strategy. First, in striving for 'reconciliation', one may simply paper over a conflict for the purposes of short-term peace, while leaving the principal reasons behind the conflict intact, thereby creating the potential for longer-term embitterment and strategic action by all parties, which ultimately undermines the appearance of agreement. Second, a very real threat to equity can arise when professionals reconcile a conflict between the powerful and the powerless and end up re-enforcing the powerful at the expense of the powerless. This tendency is very strong given the fact that professionals have little to gain personally from any radical re-structuring of power relations. Despite these important caveats, mediation has become even more critical for the success of health promotion in the future, especially in relation to the new global, multilayered context of health governance that the *Bangkok Charter* (WHO 2005) has set out to address and which will be discussed later.

The *Ottawa Charter* action areas

The priority action areas of the *Ottawa Charter* were identified as those areas that were seen at the time of the charter (and still to this day) as critical arenas for health promotion's strategic activities. We will not try and survey the myriad accomplishments of health promotion activity; rather, consistent with our general approach, we will offer a few critical comments on each action area:

Building healthy public policy

There are three elements of healthy public policy emphasized in the *Ottawa Charter*:

If, as the Lalonde Report (1974) argued, the determinants of health lay mainly outside healthcare itself, then policy action must come from policy sectors other than health. The health sector would still play an important, but not exclusive, role in public policy action to support health.
Healthy public policy requires the coordinated use of all policy levers available, including 'legislation, fiscal measures, taxation, and organizational change' (WHO 1986).
Healthy public policy requires the identification and removal of obstacles to the adoption of such policies in non-health sectors.

Without going into a long list of efforts and results in this area, the progress made can be summed up as substantial and encouraging in regard to changes in the rhetoric and discourse around health, in both developed nations and in many of the global institutions responsible for improving health and development worldwide. Conversely, one can equally characterize progress as ephemeral and demoralizing when it comes to the concrete goal of 'coordinated action that leads to health, income and social policies that foster greater equity' (WHO 1986). For a variety of reasons discussed in the later subsection on the political economy of health promotion, given the increasingly urgent crisis of widening inequities in health both between and within societies, the collective policy response of the most powerful countries on earth has been miserly and despicable. To call it 'inadequate' is a gross understatement and an unconscionable euphemism.

When *action* finally starts to catch up with some of the lofty rhetoric behind the calls for 'health in all policies' (Ståhl et al. 2006), health promotion can begin to find some satisfaction in the area of building healthy public policy. The COVID-19 pandemic which started in 2020 has seen many governments in high-income countries adopt social and economic policies which would fit under the rubric of Health in All Policies including increased income support, free childcare, and support to workers to maintain their employment. The WHO (2010) is supportive of and is promoting the use of the Health in All Policies approach. We will discuss some of the latter recent developments in relation to the *Health in All Policies* movement in a later section.

Creating supportive environments

This area forms the basis for what is called the *socioecological* approach to health. Here it is asserted that both the natural and built environments are inextricably linked with people's health. It is crucial to understand that the conceptualization of supportive environments given here is consistent with the expanded, positive understanding of health as a 'resource for everyday life'. It is not merely about threats to physical health, but involves creating conditions that allow people to have 'living and working conditions that are safe, stimulating, satisfying, and enjoyable'. This entails the complex relationships between rapidly changing technologies, working conditions, resource use, climate change, urbanization, and health (among others). At the 2019 global meeting of the International Union for Health Promotion and Education was on the theme *Promoting Planetary Health and Sustainable Development for All* and demonstrated the extent to which the international health promotion community has embraced the need to ensure planetary health. The conference statement defined planetary health in a holistic way:

> Planetary health is the health of humanity and the natural systems of which we are part. 1 It builds on Indigenous peoples' principles of holism and interconnectedness, strengthening public health and health promotion action on ecological and social determinants of health. It puts the wellbeing of people and the planet at the heart of decision-making, recognising that the economy, as a social construct, must be a supportive tool fit for this purpose in the 21st century. (IUHPE 2019)

In considering progress, past endeavours, and future prospects in this area, one must take into account the lofty ambition (and some would say naïvety) of this programme of action. As a project of knowledge development, its referral to the ‘complex interrelatedness’ of contemporary societies is but a cipher for the entire corpus of theoretical and empirical dispute and debate within the social sciences over how to characterize what are now acknowledged to be multiple, interrelated, global, national, regional, and local processes of socioeconomic and cultural change (Held et al. 1999). Later we consider some recent moves towards adopting complexity science and systems thinking to more adequately address this complex interrelatedness.

In the real world, we are not able to coordinate all the best knowledge sources available and neatly calculate what is best for health. Instead, we are left with tools like ‘health impact assessment’ (HIA) and health equity impact assessment (Povall et al. 2014). The action area of creating supportive environments can be seen as a great boon to academic productivity, both theoretical and empirical; yet, before the final judgements of the academy can be handed down, actions must be taken and decisions must be made.

Communities and developers, politicians, and bureaucrats must decide whether to build this or that highway, licence this or that mining operation, enact this or that employment regulation, and build this or that oil pipeline. We are thus forced, by the necessity to decide and act, into an inevitable reduction of complexity. The question is not whether this is a good or bad thing; it is *how*, by what *process*, is complexity reduced? Whither participation and empowerment in a field dominated by professional expertise and the cloistered secrecy of executive and administrative decision-making in both the public and private sectors?

We argue *against* the implication that instruments like HIA inevitably involve participatory processes (Kemm 2006). The natural tendency is always to define ahead of time, objectively, what elements of the built or natural environment are most important for enhancing people’s health. From a utilitarian perspective, locally defined needs and wishes may even legitimately be ignored in the name of some greater good for a larger population. However, health promotion should always err primarily on the side of the fundamental value of the autonomy and the dignity of people and their communities. In this mode, participation is foundational, even in

what are prima facie obvious areas for the guidance of refined professional expertise. In enquiring into the best way to protect and enhance the built and natural environment for health, the first step is to find out what people actually identify as the things that would make life ‘safe, stimulating, satisfying, and enjoyable’. From the professional perspective this route has one incontestable drawback: people are inevitably confused, ignorant, inconsistent, contradictory, and even just ‘wrong’. ‘People’ will disagree with each other; will get annoyed or, even worse, angry; will disrespect experts, politicians, lawyers, and any number of people who ‘actually know’ about the issue. What is feared here is what is fondly called deliberative politics; in other words, the foundation of democratic civil society.

We are, as is universally acknowledged in the health promotion community, a long way from creating supportive environments for health, especially for those suffering gross inequities in social conditions and in consequent health outcomes. What is less often acknowledged is that part of the reason this is so difficult is that we consistently exclude the very people we are meant to be helping from determining the goals, and strategies necessary to move from here to there. Once again, we are led to believe that the ends can justify the means; we can have non-participatory processes as long as we intend to make changes to enhance the lives of the less fortunate. That we end up in a place we did not intend, is inextricably linked to the fact that, at crucial junctures, when inevitable changes of directions and compromises are made (local development processes are a prime example), the people who have an inherent interest in speaking up for the powerless (the powerless themselves) are nowhere to be seen, or are barely heard.

Strengthening community action

This action area is at the very heart of health promotion; in fact, it can be argued that this action area is the one where the basic principles of health promotion lie. You can imagine (wrongly) participation, equity, and empowerment to be contingent add-ons to the other action areas; with strengthening community action the essential unity of all the values of health promotion are embedded as necessary features of its realization. Indeed, what we see in this area is the place where the true spirit of health promotion is anchored in community development as a process. In fact, in

the *Ottawa Charter* itself, there is a strange ellipsis where the term community development is introduced in the section on strengthening community action. It is as if one missed something: there is no linking phraseology relating community development to strengthening community action. This, we surmise, is no error: strengthening community action quite simply *is* community development.

Consider the definition of community development as agreed upon at the International Association for Community Development at a meeting in Budapest in 2004. Community development is a:

> way of strengthening civil society by prioritising the actions of communities, and their perspectives in the development of social, economic and environmental policy. It seeks the empowerment of local communities, taken to mean both geographical communities, communities of interest or identity and communities organizing around specific themes or policy initiatives. (Craig 2005, p. 3)

For a more sustained treatment of the need to recognize the central place processes of community development and empowerment should play in health promotion, Raeburn and Rootman's *People-Centred Health Promotion* is an essential reference (Raeburn and Rootman 1998). Raeburn and Rootman draw heavily, in their chapter on community development, on Meridith Minkler's important piece, 'Improving health through community organization' (1990). In this seminal piece, Minkler outlines the five principles she sees as foundational to community organization or development:

Empowerment
Community competence
Participation
Issue selection
Creating 'critical consciousness'.

As is now obvious, we have run into some of these principles already, the key to which is that the community itself has collective control over the process of identifying issues and planning how to address them. In addition, the important notion of 'critical consciousness' is raised. This refers to the need for critical dialogue in the Freirian sense (Freire 1972); this is particularly important when working with historically oppressed or disadvantaged communities.

Developing personal skills

The new wave of health promotion has often downgraded attention to this critical aspect of its mandate. The *Ottawa Charter* tells us that health promotion 'supports personal and social development through providing information, education for health, and enhancing life skills'. However, since the *Ottawa Charter*, health promoters, with some exceptions, have tended to either ignore or aim strong criticism at the developing personal skills area. This has come about for three reasons. First, as part of the critique of health education, it was argued that individually focused education approaches were generally ineffective in bringing about health promoting behavioural change; instead, a switch to an emphasis on the *social* factors that influence health was necessary to overcome the limitations of traditional counselling and other interventions circumscribed by the discipline of psychology. Second, the emphasis on developing personal skills was associated with the 'victim-blaming' element that many health promoters saw as the consequence of an interpretation of the Lalonde Report and other government documents (particularly, the approach taken in the United Kingdom under the Thatcher governments) in the context of the neo-liberal rolling back of the state's commitment to a strong social safety net. Finally, although developing personal skills is a central mechanism for empowering individuals to take control over their own health, many worried that, in this narrow approach, the *collective* strengthening of communities was adversely effected by too much emphasis on individual empowerment.

All of these concerns are legitimate, though in each of them there is a high risk that we will miss important opportunities by mistaking what are contingent tendencies for essential features.

As has recently been argued, the ignorance of, or even hostility to, work in this area may seriously damage health promotion's potential impact (Godin 2007). First, while many health education and behaviour change approaches are limited in their effectiveness, there are some demonstrably effective interventions that should not be ignored (Kok et al. 1997). Furthermore, we can learn and are learning about why some approaches in this area have not been effective. Second, the fact that this area of health promotion can be enlisted as part of a more general 'victim-blaming' culture of health promotion, does not mean it must be enlisted; in fact, to

the extent that genuinely empowering health education is taken seriously, the resulting improvements in self-esteem should work against victim blaming. Third, individual and community empowerment should not be a zero sum trade-off. It is only when an exclusive focus on individuals is emphasized that we will have the phenomenon of rescuing survivors from a sinking ship. We also note that social media is offering more and more opportunities for effective health promotion. The pervasive use and influence of the Internet and social media in nearly all parts of the world, presents new opportunities and challenges for health promotion and health education (see Chapter 4.3 for extended discussion of new communication technologies). A key feature that differentiates social media from more traditional communication processes is its interactive nature, where communications are not a one-way process, and where users also play an active role. This allows the formation of new online communities, which can enable virtual participation and collaboration among its members and lead to effective mobilization of social movements and the development of personal skills.

In summary, while we must be vigilant against the temptation and limitations of an individually focused, skills development approach, we must also re-engage with the most advanced and progressive elements in this area of work. If we fail to do this, we will jeopardize a key aspect of health promotion.

Reorienting health services

While we have made some important gains in the previous four areas, reorienting health services has proved more difficult. In general, throughout the world, health services remain medically dominated, cure and treatment focused, and individualistic. The *Ottawa Charter* states ‘the role of the health sector must move increasingly in a health promotion direction, beyond its responsibility for providing clinical and curative services’. However, ‘across the world, there appears to have been a stubborn resistance to systematic change in healthcare services and only limited examples of effective and sustainable health services reorientation’ (Wise and Nutbeam 2007). Health services need to embrace an expanded mandate which is sensitive and respects cultural needs. This mandate should support the needs of individuals and communities for a healthier life, and open

channels between the health sector and broader social, political, and physical environmental components.

Health services are broad and far-reaching, with the most complex service for health promotion being the acute care hospital setting. There has been some advancement in this area with the creation of the healthy hospital settings movement, with some research evidence that it is possible to practice from a health promotion perspective even within this particularly medically dominated environment, for nurses at least (Hills 1998). However, we want to focus in this chapter on the area where health promotion should flourish but has not as yet—primary healthcare. Many who work in health promotion would argue that the *Alma-Ata Declaration* (WHO 1978) was the precursor for the *Ottawa Charter*. These two documents share the same values, principles, and basic tenets; the *Alma-Ata Declaration* addresses health systems more particularly while the *Ottawa Charter* has a broader mandate. But it is their relationship that provides the key to reorienting health services. That is, primary healthcare is a place for health promotion to focus its energy in terms of reorienting health services. In fact, the more that health promotion disassociates itself from primary healthcare, the more we give the impression that it is in the domain of medicine, not health. 'The more health promotion becomes distinct from the world of curative care, the more the latter is allowed to continue to be seen as the real work of medicine' (MacDonald 1992).

We want to be clear that when we are talking about primary healthcare, we are not talking about primary care. These terms are often confused or used interchangeably. Primary healthcare refers to the philosophy and principles articulated in the *Alma-Ata Declaration* (WHO 1978). It calls for universal access to health services (universality) and the removal of geographic, social, economic, or cultural barriers to access (accessibility); it demands community participation in planning, operation, and evaluation of health services (participation); it requires integration across health and other sectors such as housing, education, and employment; it recognizes the power of multidisciplinary teams working as equal partners for the health of the community; it focuses on a range of services, determined by the community, that include health promotion, primary prevention, rehabilitative, and curative (essentiality); and, it demands a commitment to equity concerning issues of power and resources (equity and access). Therefore, primary healthcare resists the conceptual and operational

separation of treatment and prevention which fits the engineering model of healthcare, with prestige and often scarce resources going to clinical medicine to the neglect of prevention, promotion, and rehabilitation (MacDonald 1992). The importance of primary healthcare was reinforced by WHO in its Astana Declaration (WHO 2018).

People who work in health promotion and understand its philosophy and principles must be involved in the development and implementation of primary healthcare. Many people working in health promotion are of the opinion that health promotion and healthcare are distinct and separate entities. They are critical of health promoters who talk about healthcare or health service delivery at the same time that they are talking about health promotion. We have a different opinion: it is necessary, not only to talk but to act as health promoters to facilitate primary healthcare reform.

Besides the *Ottawa Charter* outlining our responsibility to take up this challenge, there are two other reasons why it must be people who work in health promotion who participate in the reorientation of health systems to primary healthcare.

First, the health system is controlled by the powerful. There is a hegemony that supports a predominant treatment/cure paradigm. Power resides in these structures and with the health professionals who work in those systems. So, as advocates for equity and social justice, health promoters have a responsibility to take up this challenge. If we continue to work only in the community where we are comfortable, we will avoid confronting one of the greatest challenges of our times: creating a health system that is based on the principles of health promotion. We are not neutral in this process. As Paulo Freire (1972) said, ‘washing one’s hands of the conflict between the powerful and the powerless, means to side with the powerful, not to be neutral’. Kickbusch (1989) confirms this concern. She states, ‘herein lies the great historical opportunity and challenge. Maybe health promotion can break the deadlock of the health policy debate that is basically about medical care and provider dominance’ (p. 14). As she suggests, we are well beyond the burden of proof needed to claim that health promotion is successful—we have demonstrated this through our change in attitudes towards smoking, drinking, and nutrition—even if these are mainly concerns of the middle class and of high-income countries. ‘Accountability and the burden of proof should now lie with the medical system’ (Kickbusch 1989, p. 14).

The second reason that health promoters must take up this challenge can be summarized in one question: if health promoters do not advocate for primary healthcare based on the principles of the *Alma-Ata Declaration* and the *Ottawa Charter*, what model of primary healthcare will dominate our countries?

Health promotion: history and influences

Health education

Health education plays a profound role in the history of health promotion. While it is true that health promotion is an 'essentially contested concept' claimed by a variety of different interests and actors (Green and Raeburn 1988), many of its most prolific commentators, particularly in the area of health promotion research and knowledge development, have been from the field of health education (Green and Kreuter 2005).

These writers have often been concerned with the failure of traditional health education approaches to help motivate individuals to act on health information. Following Tones, we adopt his definition of health education as: 'Any intentional activity which is designed to achieve health or illness-related learning, that is, some permanent change in an individual's capability or disposition' (Tones and Green 2004, p. 7). This refers to what knowledge, attitudes, or skills can be acquired by individuals through a variety of health education processes. In relation to health promotion, key health educators have radically restructured the traditional approaches to influencing health behaviour. Most of this work has revolved around challenging what are now seen to be simplistic and mechanical models of health belief and health decision-making. At the centre of this change has been an adoption of the concept of empowerment and an advocacy for using participatory learning processes that break down the power imbalances between health professionals and lay members of society. Crucially, the relationship between devolving control, developing self-esteem, and bridging the gap between knowledge, attitude, and behaviour is highlighted.

In relation to the overall theme of health equity, the move away from traditional health education models has been critical. Without the concept of empowerment, and the development of capacities and self-esteem, the

traditional ‘health action model’ of raising awareness and changing attitudes to health behaviours tended to exacerbate health inequalities, as the ‘prepared’ middle classes quickly adopted the new healthy practices of more exercise, less smoking, and a healthy diet. The efforts to help population groups that had both the worst health outcomes and the most intransigent health-related social conditions have not been nearly as successful.

A detailed account of these changes can be found in Tones and Green (2004). One very important aspect of his account is how health promoters can learn, as professionals, to overcome the social gap in both power and understanding between them and the groups and individuals they aim to enable and empower. As Tones notes, the ‘holy trinity’ of counselling (respect, empathy, and genuineness) is pertinent here. Often the more socioecological accounts of the health promotion process gloss over this crucial interactive aspect of health promotion. Whether it is with individuals or with groups, health promoters cannot act effectively without using highly developed skills of empathic understanding and facilitation. Particularly with group interactions, where often highly charged community issues are discussed, the professionals striving for neutrality and objectivity will find themselves unable to cope with the anger and resentment felt by people who perceive a history of grave social injustice behind their ‘health’ problems. It is important that these basic counselling skills are imparted to health promoters-in-training before they go out into communities and work with them on issues relevant to their health.

This shift in health education from an information-giving, pamphlet distribution approach to an empowerment liberatory approach has brought renewed interest in Freire’s emancipatory education paradigm (1972). Health promoters in several countries, most notably those in Brazil, have reclaimed and embraced his basic premises and have employed his dialogical problem-posing teaching strategies that help make health education more consistent with the principles and values of health promotion and the ‘new’ public health. Freire’s (1972) model of empowerment education describes a three-stage methodology consisting of listening, participatory dialogue, and action. Freire proposes that the main strategy of empowerment education, critical dialogue, requires us to engage in a process of problem-posing rather problem-solving. Problem-posing is different from problem-solving because it does not seek immediate

solutions to problems. Rather, generative themes arising from the listening phase are ‘codified’ and posed as problematics to raise group consciousness about specific issues. Wallerstein and Hammes (1991) contend that this process recognizes the complexity and the time needed to create effective solutions to societal issues. ‘An effective code shows a problematic situation that is many sided, familiar to participants and open-ended without solutions’ (Wallerstein and Bernstein 1988, p. 383). Freire describes these as ‘generative’ themes because they generate energy and motivate people to act. Freire contends that, through a process of dialogue that reflects on the generative themes raised through listening, people become masters of their own thinking in interaction with others (1972, p. 95). As Wallerstein and Bernstein explain: ‘The goal of group dialogue is critical thinking by posing problems in such a way as to have participants uncover root causes of their place in society—the socioeconomic, political, cultural, and historical contexts of personal lives’ (1988, p. 382).

Freire cautions that ‘the liberating educator has to be very aware that transformation is not just a question of methods and techniques’ (1972, p. 35). If that were the case, we could simply substitute one set of methods for another. ‘The question is in a different relationship to knowledge and to society’ (1972, p. 35).

Public health

Many health promotion researchers preface their scholarly remarks on the birth and development of health promotion with a discussion of its relationship to its older, more developed discipline, public health (Kickbusch 1986; Terris 1992). How this history is understood is perhaps the most telling aspect of how health promotion and its progress are viewed as a contemporary phenomenon. The argument developed next is that there has been a tendency within health promotion to tell a story of public health as a ‘fall from grace’—a fall from its original reforming, perhaps even zealous, focus on the social and environmental causes of ill health, to a more restrictive, preventive biomedical era, and finally, to a broader scale but narrower scope in the ‘lifestyles’ approach focused on individual risk factors and behavioural change (Kickbusch 1986). Health promotion steps into the story to herald the era of a ‘new public health’, as a sort of re-emergence of the spirit of the nineteenth-century socioenvironmental

model, with a modern gloss on the more subtle socioeconomic determinants of health. The purpose of this critical analysis is to challenge this tendency to nostalgia, and to explicate some of its continuing consequences for health promotion's rather schizophrenic relationship to public health. The 'golden age' of public health was influenced by a particular philosophical and political outlook that still finds its expression today in its most modern and rigorous proponents.

The history of health promotion conventionally begins with the publication of the Lalonde Report, entitled *A New Perspective on the Health of Canadians* (Lalonde 1974). The report was the first high-level national government document in the world to advocate for health promotion as a basic strategy for improving population health. It was influential internationally and set the stage for future debate with its concept of the *health field* as the articulation of the argument that the medically dominated healthcare system was only one and perhaps the least significant determinant of health, alongside biology, the physical and social environment, and individual lifestyles. The Lalonde Report relied explicitly for its argumentation on such critiques of the healthcare system found in 'social medicine' as those comprehensively outlined by (McKeown 1976), but which had their roots in the classic public health tradition of William Petty, Johann Frank, Rudolf Virchow, and William Farr (White 1991). The report contains not only the notable tension between an emphasis on individual lifestyles and the subsequently neglected socioenvironmental factors, but also an equal tension, given its own chapter heading, of 'Science versus Health Promotion'. Here it is made very clear that the 'science base' of the health field concept is epidemiology and, in this context, health promotion is seen as that type of action that must be taken even though the pertinent scientific questions have yet to be definitively answered. In some ways, this attitude allowed some initial breathing space for health promotion to prosper; however, by setting up this dichotomy, it ensured that, eventually, when 'science' made its accounting, health promotion would have its day of reckoning with epidemiology.

Meanwhile, many in the health promotion community, especially in Europe and Canada, were starting to develop an independent conceptual basis for their work, based on a rigorous reflection on the type of actions necessary to most effectively promote the health of individuals and communities. Much of this work evolved out of a complex internal critique

of the failure of traditional health education approaches and a more sophisticated understanding of behavioural change (Kickbusch 1986; Tones 1993). Yet, in some countries, such as Canada, the absence of a strong health education tradition contributed strongly to a more socioecological approach to promoting health (with some of its most influential leaders being sociologists and nurses, rather than psychologists and health educators). Furthermore, for a variety of complex reasons (including, again, individual leadership), much of the discourse of contemporary social movements (new leftist, feminist, gay/lesbian, environmentalist) found its way onto the official agenda of major institutions such as the WHO and Health and Welfare Canada (Labonté 1994). As has been recognized by one of the leaders in health promotion internationally, Canada provided a hybrid and fertile mixture of traditional welfare state values and innovative community activism that seemed to provide the perfect ground for a push for the new socioenvironmental approach to health promotion (Kickbusch 1994). Out of this productive interaction between European 'health promotion tourists' (Kickbusch 1986, 1994) and many able Canadian activist/public health practitioners, grew the idea and finally the accomplishment of the *Ottawa Charter for Health Promotion* (1986).

To fully understand the impact that the *Ottawa Charter* had and continues to have, it is important to see that there was a crucial transformation from the epidemiological and bureaucratic dominance of the Lalonde Report to the emerging 'more pluralistic (and messier) social-science paradigm of human and social relations' embedded in the *Ottawa Charter* (Labonté 1994, p. 86). This shift is key to understanding the constant tension between a 'scientific' approach to health promotion and the 'values' underlying the *Ottawa Charter* that is renewed whenever health promoters are asked to more rigorously account for their activities. It raises the uncomfortable question for those who, correctly, see the importance of reconnecting health promotion to the new public health, of just how 'new' the new public health is willing to be, when it comes to its underlying philosophical commitments.

This same tension underlies some of the confusion within the health promotion research community about how to relate to the more recent (Evans and Stoddart 1990) emphasis on 'population health' (Labonté 1997; Poland et al. 1998; Raphael and Bryant 2002). On the one hand, there is a justified admiration for the advocates of population health for their

influential arguments about socioeconomic determinants of health, even so far as to single out progressive population health researchers such as John Frank (Raphael and Bryant 2002). On the other hand, there is the well-articulated angst about the lack of health promotion principles within the population health perspective. The critiques of the population health perspective for its lack of emphasis on values, its weak or non-existent orientation to action, and its somewhat imperious attitude to what is to count as proper 'knowledge', are all cogent and well-aimed. The question is: why should this be a surprise? It is not enough to point out the baleful influence of a replacement ideology for health promotion. Where did it come from, and why is it so influential? Furthermore, is this newly emergent approach (Evans and Stoddart 1990) really so new? How far is it simply a modern, sophisticated renaissance of that very same 'golden era' of public health that health promoters so often return to as their intellectual and moral heritage?

Although health promoters themselves (especially Canadians, who were the ones facing this challenge directly) reacted strongly and were able to defend the rationale for keeping a health promotion focus, the more incisive critiques were often too 'reactionary' and came off rhetorically as overly defensive. A more accommodating response came from within Health Canada itself with Hamilton and Bhatti (1996) introducing the concept of *population health promotion*. This was clearly an attempt to marry these two potentially adversarial positions and to cement the term health promotion as an integral component of population health that could not be ignored.

Why is it that health promotion often seems 'behind the game' in the science debate? Partly, this is due to the fact that, as Labonté says and a *Companion to Social Theory* attests (Turner 2000), the social science world is 'messy'. However, it may also be partially true that, for too long, health promotion has neglected its need to develop an independent 'science base' having unconsciously bought into that original Lalonde dichotomy. This is becoming increasingly clearer as many of the leading proponents in the field are pushing for more intensive theoretical development, a pressure that has become especially acute as the need for demonstrating effectiveness has increased (McQueen 2001; McQueen and Jones 2007; McQueen et al. 2007). To understand why health promotion has such a complex and ambiguous relationship to public health, it is necessary to dig more deeply

into the foundations of modern public health and to unpack its driving philosophy and world view.

Politics and philosophy in public health and epidemiology

It is crucial to understand that the roots of the modern public health epidemiologists' focus on individual risk factors and randomized controlled trials (RCTs) is not in contradiction with or a deviation from the Edwin Chadwicks, the John Simons, and the John Snows of the classical public health. Rather, the full flowering of a utilitarian calculus, an uncompromising economism, and an obdurate scepticism of anything but positivistic scientific knowledge, can be seen as the late fruit of more than three centuries of development in public health and epidemiology.

There is a dilemma and prima facie paradox that health promotion faces when confronting its genealogy in the history of public health. In terms of lives saved and healthy years lived, the early public health interventions to combat the spread of deadly and debilitating communicable diseases cannot be underestimated. However, it is no accident that once the environmental risk factors of the major communicable diseases were effectively neutralized, a shift in focus took place to providing preventive, immunization measures. As Kerr White (1991) so convincingly puts it, the history of public health and epidemiology can be read as successive and iterative 'redefinings of the unacceptable'. Public health has always been concerned with an economistic and utilitarian approach to the health of the population; when things start to 'cost too much', the unacceptable becomes miraculously 'visible'. To understand this history, one has to ignore the facile disciplinary chasm between public health and economics, which has only recently and tentatively been bridged (Evans et al. 1994). While economics became progressively theoretical and mathematical, public health continued the original classical liberal tradition of reformist, practical utilitarianism, most powerfully apparent in the Benthamite tradition's attempt to rationalize government and public services. There is a great irony that the humanitarian idealism (an idealism at the core of health promotion's values base) of the British 'public health doctors', such as Haygarth, Heysham, Thackrah, Baker, and Millar, was never the driving force behind concentrated public health action (Fraser 1973).

As we will discuss in the subsection on health promotion and social justice, public health shares with economics a default, often merely implicit, utilitarian ethics. This shared history is seldom acknowledged, but it is a history that health promotion must confront explicitly. Fortunately, and ironically, recent developments in public health have brought into question the utilitarian approach, finding it inadequate, particularly in relation to the question of health inequity (Anand et al. 2004). The argument fleshed out in the following is that health promotion must forcefully engage in helping public health move in the direction advocated for by Amartya Sen and others (Anand et al. 2004).

Social movements

In this section, we briefly review one of the constitutive ambiguities at the heart of health promotion—many public health practitioners in the 1970s and early 1980s were increasingly cognizant of the lack of participatory involvement of the 'public' in public health programming.

A strong feature of the so-called 'new social movements' in the post-1968 period was a trenchant critique of bureaucratic structures and an increasingly administered society alongside the traditional leftist critique of capitalism. Some public health institutions, particularly urban public health units, decided to transform local public health practice by integrating a participatory model of programming that was heavily influenced by this antibureaucratic critique (Labonté 1994). However, as Dupéré et al. (2007) argue, despite its ambitions, health promotion is still not accurately described as a 'social movement', but rather a 'professional movement that had successfully advanced a discourse about health and the production of health'. Yet, despite this acknowledged status, health promoters have recognized that much of their effectiveness depends on very high levels of social engagement. The more recent emphasis on health in the context of globalization (Labonté et al. 2011) makes the necessity for health promotion to engage with larger social movements, particularly on the global development agenda, even more apparent.

Nevertheless, we find health promotion once again suspended between its constitutive desire to become one with the 'community' and its real position as a mediating professional fraction, often acting on behalf of formal public institutions. In the future, health promotion will have to

sacrifice some of its cherished professional neutrality to choose sides, especially in its responsibility to advocate for health. While this new form of activist engagement must be balanced with the legitimacy attained from professional status, the balance must shift quite radically, given the growing threats to health represented by the inequity of contemporary societies in a globalized world. An example of a social movement which involves many health professionals is the People's Health Movement which operates as a global network with country circles around the world. It also 'watches' international organizations such as the WHO and World Bank and comments on their policies and proposals (Baum et al. 2020).

Health promotion, health inequities, and social justice

We have, throughout this chapter, alluded to the commitment health promotion has to the principle of health equity. This is a fundamental and central value for health promoters and is often the touchstone for deciding why, where, and how to enact health promoting practice and policy. Yet, despite this nearly constant refrain, there is still confusion within health promotion about the theoretical and conceptual basis for its concern with health equity. While most, if not all health promoters, would see health equity as a basic goal of health promotion, seldom is the specific normative dimension that underlies this commitment fleshed out. The basic understanding is that health inequities are undesirable and should be eliminated because they are a set of systematic inequalities in health outcomes that are based on *unjust* inequalities of access to resources that provide for health. The *Health Promotion Glossary* describes what equity in health entails: 'That all people have an equal opportunity to develop and maintain their health, through fair and just access to resources for health.'

However, this definition begs many key questions, such as: what is 'fair' and 'just' access? And, what are 'resources for health'? While health promoters have often reflected deeply on health inequity, much of the appeal has been to an intuitive basis for supporting the elimination of inequity. We argue that this stance is no longer good enough. Health promotion must fully engage with recent work in political philosophy, particularly in the arguments surrounding the concept of social justice that have been developing since the publication of John Rawls' *A Theory of*

Justice (1971). Since Rawls' ground-breaking work, an ongoing debate has taken place concerning what is the proper approach to justice for whole societies (Kymlicka 1990; Aveneri and de-Shalit 1992). More recently this debate has been expanded to consider how we are to think of justice in the global context (Nussbaum 2006). Health promoters should pay close attention to what is at stake in these debates for two reasons.

First, without an awareness of these important arguments, health promotion is liable to accept a default utilitarianism that it inherits from public health, which in turn the latter shares with orthodox economics. It is argued here that this unacknowledged utilitarianism is in direct contradiction to two profound moral intuitions that form the core of health promotion values: that it is wrong to increase overall health at the expense of the least well off; and, that human dignity and personal autonomy are overriding values.

Second, important developments in these debates are directly relevant to concerns with acting on the social determinants of health. Recent arguments have been refined concerning why and how we should address the issue of health inequity, both within and between societies (Nussbaum 2000; Anand et al. 2004). As health promoters, charged with the responsibility to advocate, enable, and mediate for equity in health, we should be armed with the very best arguments supporting our position.

We argue here that the one of the most promising theoretical developments in political philosophy that have implications for health promotion are in the evolving 'capabilities' approach to social justice and equity (Nussbaum and Sen 1993; Nussbaum 2000, 2006). This approach most nearly matches the health promotion approach to health as a 'resource for everyday living'; according to this doctrine, the 'social bases for health' would count as a primary good, or capability that should, by right, be provided to all citizens (and by extension, all human beings) at a minimum standard (Nussbaum 2006). It cannot be assumed that arguments for equity in health are unassailable and intuitively obvious for two reasons. First, without some substance behind what is meant by equity and what kinds of resources are to be distributed equitably, the demand for equity in health can be dismissed as either empty or naïvely utopian. Second, differing conceptions of what is just will lead to different outcomes in terms of actions to promote health. For example, unless we are very clear, 'equal opportunity' can be understood in an absolute minimalist sense and can

allow powerful institutions to continue to support vast inequities in resources for everyday living. As we will see next, how we conceive of social justice has a profound impact on the types of actions we can imagine as solutions to the gross inequities in health we find across the world. Specifically, it has become apparent that the goals of health promotion are intimately related to the goals of a socially just global development agenda. Next we focus on an important element that tends to be lost in much of the discourse on health equity: what are the political, economic, and social mechanisms by which the social determinants of health are reproduced as unequal resources for health? This is followed by considering one emerging global initiative aimed at policy solutions in this area: the *Health in All Policies* agenda.

The political economy of health promotion

Much good work has been done on the 'political economy of health' (the analysis of how different politico-economic social structures affect health outcomes), yet an enormous amount is still required (Navarro and Shi 2001; Navarro 2002; Langille 2003; Raphael 2003). Furthermore, there have been some excellent analyses of the 'political economy of healthcare' (the analysis of the effect of different political and economic arrangements on the quality and differential access to health services). In this subsection, we outline a different question: what is it about our contemporary political and economic structures that vitiates against the implementation of health promotion strategies and actions as they are conceived in the *Ottawa Charter*?

To begin to answer this question, we need to consider the three fundamental dimensions to health promotion: empowering communities and individuals, building health public policy, and creating supportive environments.

As has already been argued, empowerment is a key dimension of health promotion. By its very nature, empowerment aims to rebalance existing power arrangements by enabling those currently without power to gain access to the resources necessary to live fulfilled and happy lives. In order to do this with any success, health promoters must do two things: they must have a clear-headed view of existing power structures and relations; and,

they must recognize, as professionals, how they themselves fit into those power relations and how they help, often unconsciously, to reproduce them. One way of seriously addressing this issue is to pay more attention to the concepts of class and status mentioned on the section on social justice and health promotion.

Health promotion, to be successful, must rely on concerted action by governments around the world, both within their own territories and in cooperation to address needs that require global action, such as on climate change. However, while these wishes are often articulated (WHO 2005), seldom are we offered an analysis of the structure and dynamics of the contemporary state system in a global context. A more reflective perspective is important here, as theorists of the state argue that certain issues and certain groups, using specific strategies, are more or less likely to be successful changing the nature of hegemonic projects and reversing the direction of state policies (Jessop 2002). Health promotion must become more strategic in how it operates vis-à-vis the state; it must recognize in an explicit way the limitations and opportunities available and integrate theoretical perspectives and practical actions in regard to one of its key areas: building health public policy.

Finally, creating a supportive environment is even more wrapped up in the dynamics of global capitalism than all the other areas combined. The fundamental prerequisites for health as outlined in the *Ottawa Charter* are: peace, shelter, education, food, income, a stable ecosystem, sustainable resources, social justice, and equity. These are the elements that, when in adequate supply, make up many of the properties of a supportive environment for health. Yet, each of these elements is in large part determined by the particular structure and dynamics of our global socioeconomic system.

It is necessary to develop an awareness of the fundamental political and economic drivers behind the dynamics of contemporary societies in both the developed and developing worlds. If equity in health relies on the fundamental fairness of social, political, and economic institutions, then ignoring these basic realities is no longer an option for a serious approach to health promotion. These important insights should no longer be gained in an ad hoc way but should be seen as part of what should constitute core knowledge for competent health promoters.

Social theory and health promotion

Recently, particularly following the report of the WHO Commission on Social Determinants of Health (2008), there has been a raft of activity by both academia and governments aimed at developing knowledge about the social determinants of health. There has also been a marked (and needed) shift of emphasis to what types of *action* societies need to take to address the consequences of the iniquitous distribution of resources that support health. Less prominent are attempts to confront theoretically the main causal mechanisms that produce and reproduce the social inequalities that lead to health inequities. While there have been recent attempts by some health promotion researchers to re-engage with fundamental debates in social theory (McQueen et al. 2007), for the most part the public health community as a whole, and health promotion by proxy, is still mainly dominated by the narrowly focused methodological lens of epidemiological science although there is increasing use of theory in health promotion as can we seen in recent editions of Health Promotion International (see for example Harris et al. 2017). This reluctance to confront the ghost of social theory's past is most apparent in the way that the categories of *class* and *status* are dealt with in health promotion and public health discourse. Where they are mentioned at all, they tend to be conceptualized as epidemiological variables that measure an individual or group's socioeconomic attributes or properties (e.g. income, education level, wealth, job status), not as social processes that reproduce structural disadvantages for most and accumulate power and privilege for a few (see Scambler (2012) for an excellent review of this problem). The key elements of social theory that should be at the forefront of debate in health promotion circles are considered more extensively in two recent sources (McQueen et al. 2007; Carroll 2012).

The *Health in All Policies* movement

Launched as Finland's main theme of its 2006 European Presidency, *Health in All Policies* (HiAP) is a strategy to help link health and other policy sectors in an overarching intersectoral approach to improving health and well-being and reducing health inequity (Leppo et al. 2013). It is aimed at reinvigorating the original emphasis in the *Ottawa Charter* on healthy public policy, and to follow up on the work done at the WHO conference in

Adelaide, Australia in 1988 (WHO 1988). Since that meeting, there has been much reflection on both the details of how to implement healthy public policy and the particular challenges posed by integrated, coherent, intersectoral action for health. More recently, the WHO reconvened in Adelaide to produce an international statement on HiAP called the 'Adelaide statement on health in all policies: moving toward a shared governance for health and well-being' (WHO 2010). It is no coincidence that it lays heavy emphasis on 'governance'. This was followed by two important publications in 2012, also focusing on governance (Kickbusch and Gleicher 2012; McQueen et al. 2012). The central challenge of implementing HiAP has been the difficulty of managing the governance and accountability structures necessary to sustain both vertical (levels of government, non-governmental, and private sector) and horizontal (cross-ministry, interdepartmental) intersectoral collaboration. We are only now beginning in public health and health promotion circles to appreciate the different type of knowledge base required to assess the effectiveness of policy implementation. We are still largely stuck in an outmoded attempt to squeeze what are really matters for political science, economic sociology, and the sociology of the state into the narrow methodological confines of standard epidemiological research designs. Increasingly (Lawless et al. 2012; Carroll et al. 2013; Baum et al. 2017) HiAP Research applies political theory case studies of HiAP in order to better understand the key mechanisms underlying success and failure. Clearly, HiAP is required to move forward on the intersectoral action agenda outlined in the *Ottawa Charter*; however, improved knowledge on implementation and sustainability are required the future.

Complexity, context, and causality in health promotion research

Over the past 15 years, a series of publications have charted the specific methodological challenges for evaluating the effectiveness of health promotion interventions (IUHPE 1999; Rootman et al. 2001; Zaza et al. 2005; McQueen and Jones 2007). There has been some scepticism about applying the methodological protocols of evidence-based medicine (EBM) and RCTs as the gold standard because of the problems of complexity and context (McQueen 2007). One emerging alternative has been to use

different methods for synthesizing evidence, such as the realist (Pawson et al. 2005) or meta-narrative (Greenhalgh et al. 2005) review approaches. A more detailed treatment of these latter approaches is beyond the scope of this chapter; however, one further potential for advancing beyond traditional EBM-type methods, is in the use of so-called 'systems thinking' or 'complexity science' to understand the rich complexity and contextual subtlety of the settings within which health promotion interventions take place, and of the interventions themselves.

Key to understanding the critique of EBM and some of the proposed alternative strategies is the different nature of how causality is conceptualized. The realist alternative has a direct, philosophical critique of the underlying empiricist-positivism of EBM's approach to causality (Bhaskar 2008) and has been applied to health promotion Baum et al. 2019). Conversely, systems thinking and complexity science approaches are more concerned with EBM's inability to take account of the interactive, emergent, and non-linear dynamics of causation that are crucial to understanding health promotion interventions as complex adaptive systems that intervene in the context of settings that are themselves complex adaptive systems.

Some health promotion researchers have started to take seriously the potential for a complexity or systems approach to health promotion interventions (Rickles et al. 2007; Shiell et al. 2008; Hawe et al. 2009; Trickett et al. 2011). These emergent attempts to apply complexity science have yet to show fruit (though systems thinking in public health has a longer pedigree), yet they hold much potential to transcend the current impasses in health promotion effectiveness research.

Conclusion

We have attempted to offer the reader a chance to reflect on a set of core conceptual issues that underlie the health promotion problematic. The five key messages we want to impart about health promotion are listed here:

Health promotion is a complex, often ambiguous concept and set of practices. Health promotion finds its core values and principles in the Ottawa Charter which bears careful examination to comprehend the essence of health promotion.

Health promotion has an intimate connection to health education, with many of its most important and prolific thinkers having a health education background. The revolution in health education practice is directly connected to the birth of health promotion but beyond this, health promotion has its roots in the deep history of public health and has been invigorated by contemporary social movements.

Health promotion is fundamentally about ethics, values, and social justice. Only secondarily is it about technical strategies for behaviour change. The foundational principles of health promotion are *equity*, *participation*, and *empowerment*.

Health promotion is a professionally dominated movement. This requires health promotion professionals to be critical and reflexive in their practice; they must acknowledge power imbalances that favour professional dominance and work to restore power to individuals and communities.

Health promotion must take its duty to enable people to control the determinants of their health seriously. To do this it must engage more directly with contemporary arguments in political philosophy and it must be aware of the dynamics of the global political economy and its effect on the potential for health promotion.

Some of these issues are well known, such as the problem of professional dominance; while others, such as the political economy of health promotion, or the engagement with political philosophy, are not addressed or require much deeper reflection.

We have argued that, at its heart, health promotion is about a radical shift in values for public health. It is not that public health was never concerned with equality or alleviating the misery of the poor; arguably, the so-called ‘golden age’ was driven by exactly these moral questions. However, these intuitive commitments were not sufficiently followed through when it came to not just *what* outcomes to change but *how* to change them. Too much of public health, for too long, was driven by a benevolent paternalism that, particularly when it came to dealing with chronic diseases and with vulnerable populations, ended up being counterproductive. Indeed, not only

was this paternalism ineffective in many areas, it was unethical. It assumed the authority of experts and professionals, not only to determine technical solutions, but to determine needs. If we are to take the concepts of equity and empowerment seriously, they have profound implications for how we do public health interventions. We have learned that by addressing needs without first establishing a participatory framework that enables individuals and communities to determine those needs for themselves, we fatally undermine one of the most crucial capacities for health: human dignity and self-respect. This is particularly so in communities that have suffered historical social injustices. As Richard Sennett says, people subjected to this disempowering process, experience 'that peculiar lack of respect which consists of not being seen, not being accounted as full human beings' (Sennett 2003, pp. 12–13).

We hope to have demonstrated that there are many barriers to realizing this change in power relations; yet, there are also very important opportunities, such as with the Millennium Development Goals and the Commission on the Social Determinants of Health, where there is an increasing clamour for action to redress health inequities through empowering processes. It is notable that even the World Bank, often the subject of brutal criticism for exacerbating inequalities (Stiglitz 2003), has made significant moves towards recognizing the importance of reducing inequity in human development and has integrated an empowerment approach (World Bank 2006). It remains to be seen whether these gains can be translated into major policy changes and effective implementation; nevertheless, it is at this level where health promoters and all public health practitioners and researchers must have a strong advocacy position.

We hope that it is apparent that, in our interpretation, health promotion is much more than a set of technical public health interventions aimed at revamping traditional health education for the twenty-first century. We cannot let go of the core competencies built up by health education and other contributing fields, but we cannot be limited in our vision either. Health promotion has to face up to the fact that, while it may only be a junior partner in the global struggle to develop a more just and equitable world, when it comes to a key human capability and resource, *health*, it must take a lead role in making the argument for equity, develop and present the evidence for what *action* is necessary to achieve equity in health, and finally, to hold the powerful accountable where they fail to live

up to the demands of justice for health. Embedded in health promotion is an imperative to act ethically and justly. In this case, unlike most, there is no choice.

Development and evaluation of complex multicomponent interventions in public health

Rona Campbell and Chris Bonell

Introduction

There have been notable advances in developing the evidence base in public health to support decision-making in policy and practice (Academy of Medical Sciences 2017; United Kingdom Clinical Research Collaboration 2018) including successful funding initiatives in the United Kingdom specifically designed to enhance the quality and quantity of public health research and to support research capacity development (United Kingdom Clinical Research Collaboration 2018; National Institute for Health Research School for Public Health Research n.d.; White 2018). Nevertheless, at a time when health systems worldwide are struggling to respond to the burden of disease and demand for healthcare, the need for innovative, cost-effective public health interventions remains (Corbett et al. 2018). Several challenges to developing and evaluating such interventions are apparent.

Firstly, policy interventions which have the greatest capacity to improve population health (for example, increasing the price of unhealthy food or beverages to tackle obesity), are more difficult to formulate and implement than interventions merely promoting individual behaviour change because of the political commitment required (Swinburn et al. 2011). Furthermore, policy interventions are often introduced with little thought given to evaluation, missing opportunities for evaluators to work with stakeholders to identify what questions an evaluation could usefully address, collection of baseline data, identification of suitable control conditions, and the possibility of randomizing to intervention and control conditions.

A second challenge is the need for evaluations of public health interventions to attend to the contexts in which interventions are

implemented and received (Craig et al. 2018) and how this might affect their intended and unintended impacts, the latter including effects on the broader functioning of the social 'systems' operating within different contexts (Rutter et al. 2017), which we shall consider in more detail to follow. A third challenge is the need for the development and evaluation of interventions to involve collaboration between researchers, the public and public health policymakers, and practitioners, to maximize the relevance, acceptability, and rapid scale-ability of interventions. In this chapter, we consider how these challenges can be addressed as we describe methods for developing and evaluating complex public health interventions. We begin by examining what complexity means in the context of public health.

Definition and scope of the concept of a 'complex intervention'

A simple intervention is generally characterized as involving a s single component with effects unlikely to vary by context (Petticrew 2011). By contrast, complex interventions involve several synergistic interacting components whose effects are irreducible to a single 'active ingredient'(Medical Research Council 2000). More recent literature suggests that complexity can arise from the number and difficulty of behaviours required by those delivering or receiving the intervention, the number of groups or organizational levels targeted by the intervention, the number and variability of outcomes, and the degree of flexibility or tailoring of the intervention permitted(Craig et al. 2008; Skivington et al. 2021). Accordingly, all public health interventions must be regarded as complex.

Complex interventions or complex settings, contexts, and systems

In contrast to the aforementioned literature, it has also been recently suggested that complexity, rather than describing the characteristics of a particular intervention, actually describes how interventions interact with local contexts or 'systems' (e.g. family, school, community, country) (Hawe et al. 2009; Skivington et al. 2021).

Interventions with several interrelated parts, addressing multiple levels or requiring multiple new behaviours, it has been suggested, may be more

helpfully thought of as complicated rather than complex. Complexity, so the argument runs, is a property of the system that an intervention is trying to change, not an inherent feature of the intervention itself (Shiell et al. 2008). Complex systems have properties emerging from the mutual interactions of multiple ‘subunits (that are often composites themselves) whose repeated interactions result in rich, collective behaviour that feeds back into the behaviour of the individual parts’(Rickles et al. 2007, p. 933). Interventions, whether simple or complicated, can be thought of as interruptions to such complex systems, with the implication that their local impact will be context-dependent and affected by recipient or provider factors (Lewin et al. 2017). For example, Project Northland in the United States used schools as a setting for a health promotion intervention to discourage alcohol use by young people. It involved making changes to elements of the school curriculum, changing the school environment, and engagement with parents and the wider community to restrict both access to and demand for alcohol (Perry et al. 2002). The intervention is clearly a complicated one, but its impacts within schools are also complex. Schools were not simply the setting for delivery but were each complex systems, involving a whole series of different types of subunits (e.g. students, teaching staff, classes, buildings), which the intervention aimed to ‘interrupt’ in multiple ways in order to reduce alcohol use. The schools were also part of a wider community, another complex system, on which the intervention was also intended to have an impact.

When developing a public health intervention, it can be instructive to understand something of the nature of complex systems, and to think of an intervention as something that is intended to disrupt the system. Doing so can help ensure that the likely mechanisms for achieving change, the potential consequences of disrupting the system (both intentional and unintentional), and the interaction between the intervention and the context in which it is being implemented (Moore et al. 2015) are all carefully considered from the outset.

This increasing interest in systems science and how it might inform the development and evaluation of public health interventions results has several important implications. Firstly, those developing public health interventions should focus not merely on engendering individual behaviour change but also on transforming entire social systems (for example, urban planning, housing, and welfare policies) so that these promote rather than damage

health (Rutter et al. 2017). Secondly, a focus on one or two primary health outcomes might be broadened so that evaluations explore broader impacts on system functioning and how this affects those involved in these systems. For example, evaluations of school-based health curricula might continue to examine direct effects on students' health knowledge and behaviours but also explore how delivering the curricula affects staff workload and mental wellbeing, or student engagement with education. Thirdly, we might revise how we think of interventions; rather than discrete entities with clear starting points and modes of delivery which can 'manualized', public health interventions are often routine, constantly adjusted, and intermingled, so disentangling the effect of any part is difficult. Fourthly, while it remains useful to estimate intervention fidelity and effects within rigorously conducted studies, it is important to appreciate that the same fidelity and effects might not manifest when the intervention is delivered across other systems that vary across time and space. The overall implication of this is that evaluations will be most useful when they enable development and refinement of theories about how intervention can interrupt systems in ways that promote health' (Rutter et al. 2017) and how this will vary across contexts' (Egan et al. 2019, p. 14)

But such theories are always likely to be imperfect because of the properties of systems. Firstly, systems are adaptive and will likely adjust in response to the implementation or even suggestion of a new intervention. For example, when the UK government announced the introduction of a tax on sugar-sweetened beverages, some producers began to reformulate the sugar content of their drinks before the legislation came into effect. Secondly, as already mentioned, systems will have emergent properties arising from dynamic interactions between their components. For example, herd immunity, where a critical mass of individuals is immune to an infection such as through vaccination, is a property of a population system arising from infection-host interactions which confers benefits on individuals who might themselves lack individual immunity. Thirdly, systems often include feedback loops, where one change enhances, balances, or diminishes another. For example, the introduction of compulsory charges on plastic bags in shops in the United Kingdom to reduce plastic pollution has led directly to a huge decline in their use and shifted cultural norms towards reuse, perhaps contributing towards the popularity of other forms of reuse and recycling. Fourthly, systems are characterized by non-linear dose-responses. For

example, in an attempt to induce system level change in the secondary prevention of key non-communicable diseases in the United Kingdom, since 2009 there has been very substantial investment in the NHS Health Check programme. All those aged 40–74 years are invited to attend their general practice for checks relating to stroke, kidney disease, heart disease, type 2 diabetes, and dementia, and for measures to reduce risk of adverse outcomes to be taken. However, despite the substantial financial input (or dose) the response has been disappointing with a recent evaluation concluding that 'program performance was substantially below national and international targets' (Chang et al. 2016).

Standardized or flexible interventions?

When the UK MRC first published a framework for the development and evaluation of complex interventions (Medical Research Council 2000) it adapted the phases undertaken in drug development and testing and proposed that 'once the RCT has begun, the intervention must not evolve, as the RCT results will be unusable if later participants experience a different intervention than earlier ones. Fidelity to treatment protocols or quality standards may be essential to effectiveness' (Medical Research Council 2000, p. 11). This emphasis on testing a standardized intervention, implemented with a high degree of fidelity, caused some concern because, it was thought, public health interventions might be maximally effective if they actively encouraged appropriate tailoring to local circumstances. Such a view led some to conclude that randomized trials were therefore not a suitable method for evaluating public health and health promotion interventions (McNulty et al. 2013). As Hawe and colleagues (Hawe et al. 2004) pointed out, however, this concern was based on a misconception of what is standardized. She argued that what should be standardized is the function of the intervention and the steps in the process by which change is to be achieved, not that all the components of an intervention have to be delivered in exactly the same way to each person, or in each setting. Hawe and colleagues did not reject the randomized trial as a method of evaluation but argued that 'instead of mimicking trial phases which assume that the 'best' or the 'ideal' comes from the laboratory and gets progressively compromised in real world applications, community trial design would start by trying to understand communities themselves as complex systems and

how the health problem or phenomenon of interest is recurrently produced by that system' (Hawe et al. 2004, p.1562). A pragmatic solution to the problem of artificial standardization, however, is to simply embrace the idea that the interventions we develop and evaluate have adaptation and evolution built into them. This matter is discussed in further detail in the later subsection on fidelity.

Simple or complex research questions and questions from different research perspectives

Evaluations can address simple or complex questions (Petticrew 2011). For example, a local authority commissioner might wish to evaluate an obesity prevention programme comprising multiple components: health education for pregnant women to encourage breastfeeding and healthy weaning; provision of healthy food and opportunities for physical activity among children under the care of nursery schools, child minders, and day care; classroom-based education on nutrition and physical activity in primary schools; and local spectator sports clubs encouraging fathers to be physically active and eat healthily with their children. A commissioner may simply wish to know whether or not the overall programme has been effective in reducing rates of obesity. Or she may wish to know: for which subpopulations of children and in what settings it was effective or ineffective; whether there were important secondary outcomes such as reductions in adult obesity; whether certain components interacted to achieve particularly strong effects; or whether there were broader benefits or harms, such as a reduction in the number of fast-food outlets in the locality due to a drop in demand.

The research question might also be informed by the research perspective(s) of those doing the evaluation. The latest draft MRC guidance on the development and evaluation of complex interventions suggests four different perspectives on a continuum from efficacy to systems considerations each asking different but not mutually exclusive questions: '*Efficacy perspective*—To what extent does the intervention produce the intended outcome(s) in experimental or ideal settings? *Effectiveness perspective*—To what extent does the intervention produce the intended outcome(s) in real-world settings? *Theory-based Perspective*—What works

in which circumstances, and how? and *Systems perspective*—How do the system and intervention adapt to one another?' (Skivington et al. 2021)

Intervening at different levels and within systems to improve the health of populations

The importance of multilevel and multifaceted interventions was set out in both the 1986 *Ottawa Charter for Health Promotion* (WHO 1986) and the later *Bangkok Charter* (Anonymous 2006) so that interventions should aim both to address individual, 'downstream' determinants of health such as knowledge and attitudes, as well as community and societal 'upstream' determinants, such as exposure to health benefiting and health harming goods and services, and social inequalities in wealth and power. When designing complex public health interventions, the socioecological approach to public health described by McLeroy and colleagues (Kenneth et al. 1988) with its origins in the work of Bronfenbrenner (Bronfenbrenner 1974) on ecological systems theory, can provide a useful framework for thinking about the different levels of intervention. This socioecological framework was designed to focus attention on social and environmental factors as targets for health promotion. It identifies five complementary levels of change, targets, and approaches which are set out in Table 6.5.1.

Historical evidence suggests that the greatest improvements in public health have been achieved through non-medical interventions, such as improved sanitation, welfare benefits, and improved workplace safety (McKeown 1976). More recent evidence also indicates that multifaceted and multilevel interventions are more effective than those operating at a single level (Greaves et al. 2011), and that environmental level interventions are more likely to be cost-effective than individually targeted clinical or non-clinical prevention interventions (Chokshi and Farley 2012). Reviews of the use of socioecological models in health promotion since the late 1980s have, however, suggested that published evaluations still tend to focus on one or two levels of intervention (Richard et al. 2011; Golden and Earp 2012), although there has been a notable increase, in interventions with multiple and more 'upstream' targets, such as the community or political environment (Richard et al. 2011; United Kingdom Clinical Research Collaboration 2018).

Table 6.5.1 Socioecological framework

Level of change	Target	Approach
Intrapersonal	Individuals	Changing individuals by changing their knowledge, attitudes, values, motives, skills, and behaviour
Interpersonal	Small groups such as the family, work colleagues, friendship groups	Achieving change through formal and informal social networks and peer groups by changing group norms or the group culture
Institutional	Organizational settings such as schools, colleges, and workplaces	Achieving change via organizational policies and rules, and by creating healthier organizational cultures and environments
Communities as mediating structures, relationships among organizations, and as geographical entities with political power	Neighbourhoods, community organizations	Achieving change through collective action by working with community organizations that are sources of social capital, coordination and coalition building between organizations, and increasing the representation of disadvantaged population groups on community decision-making bodies
Public policy	Whole populations at local, regional, national, and international level	Achieving structural change through the development and implementation of health promoting local-, regional-, country-, and international-level policy, and legislation

(United Nations General Assembly, 2015).

Health inequalities

Public health has the dual goals of improving population health and reducing health inequalities between different populations. The United Nations' *2030 Agenda for Sustainable Development* has health and wellbeing as one of 17

goals the achievement of which is integrally linked to ending poverty and hunger, planetary health, maintaining peace, ensuring prosperity, and achieving dignity and equality for all (United Nations General Assembly 2015). One approach to tackling health inequality is to target interventions at disadvantaged groups at high risk of morbidity or mortality. This can be problematic, both because it can sometimes be stigmatizing and even harmful, but also because even if effective in reducing these groups' risk it may be insufficient in bring about substantial population-level reductions in risk because, as Geoffrey Rose pointed out (Rose 1981), where disease risks follow a bell-shaped curve (as is the case with almost all non-communicable disease), the majority of cases of a disease will arise from those at low or medium risk (because there are simply more of them). However, universalist approaches which do not address the 'upstream' determinants of disease and only address individual behaviour may have the potential for widening inequalities because of the 'inverse prevention law' (Gordon et al. 1999) whereby socioeconomically advantaged groups often benefit disproportionately from universal interventions. In particular, interventions requiring action from recipients, such as interventions to reduce obesity requiring participation in weight-loss schemes or interpretation of nutrition labelling, are likely to benefit those most able to take such action, therefore more likely to widen inequalities. Interventions less demanding of individual actions, such as governmental measures to reduce the sugar and fat content of food or increase the affordability of healthy food (Adams et al. 2016; Rutter et al. 2017) are more promising means of benefiting disadvantaged populations. Progressive universalism has been advocated, for example, by the *Marmot Review*, as a way of avoiding these difficulties by ensuring that action on health inequalities both addresses 'the causes of the causes' but also by ensuring that the scale and intensity of more downstream interventions are proportionate to the level of disadvantage (Marmot 2010).

These matters must be examined empirically within evaluations. Evaluations of the free-swimming initiative for children in England and of the introduction of universal access to free leisure facilities in the north-west of England are good examples of evaluations examining whether the inverse prevention law was operating. In both cases findings showed that physical activity could be increased and inequalities reduced. (Audrey et al. 2012; Higgerson et al. 2018).

When developing public health interventions, it is therefore important to consider their potential for narrowing or widening health inequalities, and to ensure that evaluations assess whether factors such as socioeconomic status, gender, or ethnicity moderate (statistically interact with) intervention effects. Both the evaluations of physical activity interventions described earlier used large administrative datasets which provided the statistical power to for such moderator analyses. It is important to pursue such analyses, even in the absence of sufficient statistical power, because the findings can contribute to the accumulation of evidence in systematic reviews of the likely impact of particular interventions on inequalities (Tinner et al. 2018).

The PROGRESS acronym (Evans and Brown 2003) indicates disadvantage may be related to place of residence, race/ethnicity, occupation, gender, religion, education, socioeconomic status, and social capital and is a helpful prompt to thinking about which factors are relevant to the population for which the intervention is being designed. The Health Inequalities Assessment Toolkit (NIHR CLAHRC North West Coast 2017) is another useful resource for this purpose.

Stages in the development of complex interventions

Several guides relevant to the process of intervention development have been published recently. These include a taxonomy of approaches to developing health improvement interventions (O'Cathain et al. 2019), guides to the process itself (French et al. 2012; Wight et al. 2016; Hawkins et al. 2017) guidance on considering context in relation to population health interventions (Craig et al. 2018) and a framework for reporting the details of complex interventions in a standardized way for replication, transfer and evidence synthesis purposes (Hoffmann et al. 2014). The taxonomy of approaches to intervention development is based on a systematic review and synthesis of relevant literature from which the authors identify and describe eight categories of approach to intervention development and 18 different actions which can be taken within each approach (O'Cathain et al. 2019). The strengths and weaknesses of each approach are identified. This compendium is very detailed and covers the development of clinical and patient-based interventions as well as those with a population health focus. Next we outline the key stages in the process of complex public health intervention development.

Review of existing quantitative and qualitative evidence

A first practical step in developing a complex intervention, whether designing something new or modifying an existing approach, is to review the available evidence. If there are already relevant systematic reviews, it may only be necessary to read these or update them. But if not, a new review may be needed (see Chapter 5.13 for further information about systematic reviews). While systematic reviews of quantitative evidence of intervention effects will summarize what is known about the effectiveness of a particular intervention, it is also useful to review relevant qualitative or quantitative research on implementation, which may provide important knowledge about the contexts in which the intervention has previously been used and how context might influence the feasibility, acceptability and therefore potential impact of the intervention (Craig et al. 2018).

Public involvement from the outset

Including potential beneficiaries in intervention development is vital in ensuring that the intervention is relevant and acceptable. In the health and social care sectors, pre-existing groups representing particular patient and client groups can be engaged as partners in research, though the extent to which they are representative of all potential beneficiaries is often uncertain. In public health, identifying representative groups, particularly for universalist interventions, may be even more challenging. There is, however, guidance available on how to approach this and examples of good practice. INVOLVE is part of the National Institute for Health Research in the United Kingdom and its role is to encourage, support and set standards for public involvement in health research (INVOLVE 2017). Its website provides ample guidance for researchers (http://www.invo.org.uk) and the public. Involvement in public health research can and should, where relevant, include children and young people (Bird et al. 2013) and there are specialist groups set up who can provide such input. The ALPHA group (Advice Leading to Public Health Advancement) is one such example. This specially trained group of young people meets monthly to provide input into research undertaken by the DECIPHer public health research centre and other research organizations (DECIPHer, n.d.).

Involving policy and practice partners from the outset

Consulting or collaborating with those who determine policy about or actually deliver similar interventions at this early stage will also provide useful insights. Involving such stakeholders from the outset is also more likely to result in its successful translation from research into routine practice if evaluation of the intervention suggests it is effective and cost-effective. System mapping is increasingly being used in stakeholder consultations to help identify what factors are thought to contribute to the public health problem to be tackled, to consider how and where to intervene, and what resources might be leveraged and deployed to address the problem. Such system maps can also be used to guide evaluations as in the example to follow (Fig. 6.5.1), which was used to inform the design of an evaluation of the health impacts of the UK Treasury Soft Drinks Industry levy (SDIL) (White 2017).

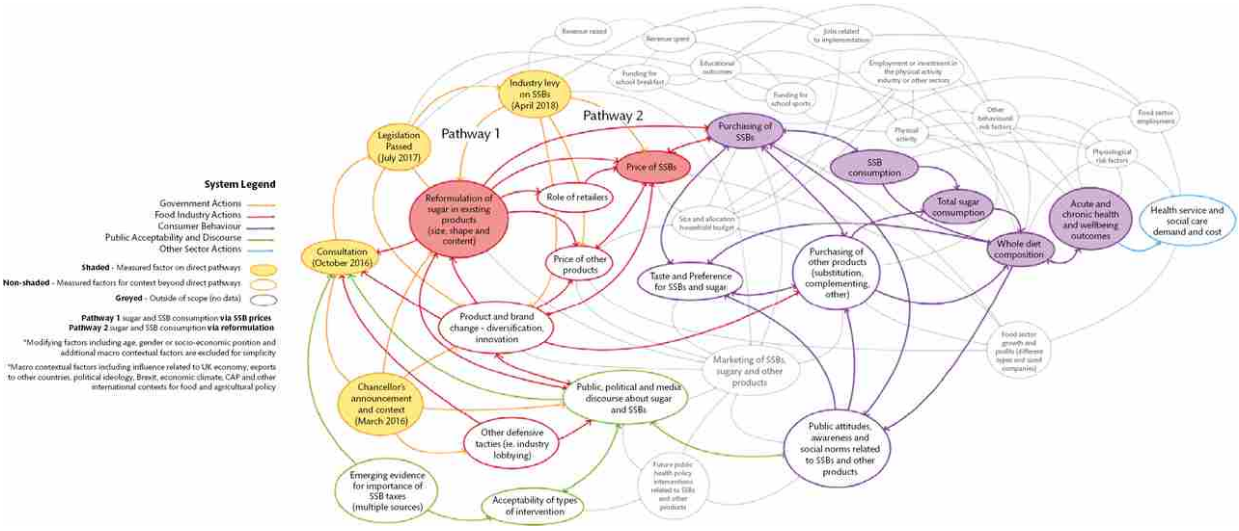

Fig. 6.5.1 System map for the evaluation of the health impacts of the UK Treasury Soft Drinks Industry Levy.

Importance of theory

Pawson and Tilley (1997) suggest all interventions are 'theories incarnate' because they assume that a certain action (or intervention) will trigger mechanisms which, in combination with the conditions that prevail at the time (context), generate particular impacts (or outcomes). However, such assumptions may remain implicit and the opportunity for evaluation to test them and thus contribute to the refinement of middle-range theory may be lost (Moore and Evans 2017). Guidance on developing complex interventions advocates using explicit theories of change to inform their design (Campbell et al. 2007; Craig et al. 2008; Glanz and Bishop 2010; Skivington et al. 2021). While interventions formulated without recourse to theory can and do work, there is evidence that interventions are more likely to be effective when informed by theory (Noar et al. 2008; Glanz and Bishop 2010). The ASSIST peer-led smoking prevention intervention is an example of a successful theory-based smoking prevention intervention (Campbell et al. 2008). Students aged 12–13, identified by classmates at secondary school as being influential, are trained to have conversations with their peers about the benefits of not smoking (Audrey et al. 2004). The intervention was informed by diffusion of innovations theory (Rogers 1995) with the peer supporter's role being to diffuse new attitudes and new norms of behaviour relating to smoking throughout the year group. A cluster RCT conducted in south Wales and south-west England showed a 22% overall reduction in the odds of being a smoker in intervention compared with control schools. More detailed follow-on research on the peer supporters found that those who are asked to work informally, rather than under the supervision of teaching staff, engaged more effectively with the task they have been asked to undertake and more effectively diffused the health-promotions messages, in this case smoking prevention (Audrey et al. 2008).

The ASSIST intervention drew on a theory from the social sciences. Taking theories 'off the shelf' to inform intervention development is a common but potentially problematic approach because of a tendency for researchers to choose popular psychological or behavioural theories which may not be altogether pertinent to the mechanisms through which the problem is actually sustained (Moore and Evans 2017). For example, the Gatehouse whole-school intervention aimed to promote mental and physical health among adolescents by rendering school environments more inclusive and engaging but was informed by Bowlby's attachment theory which focuses on dynamics between mothers and infants (Patton et al. 2003). This

tendency is confirmed by reviews of which theories have been utilized most frequently in public health interventions. These show that the field is dominated by psychological theories (Shahidullah 1995; Glanz and Bishop 2010; Davis et al. 2014). However, as we have already indicated, effective public health intervention is likely to require action at more than just the level of the individual, needing to be informed by a clear understanding of the workings of the social system that sustains the public health problem to be tackled. Public health intervention research may therefore need to draw on theories from a variety of disciplines. There are useful resources available which provide compendia of theories but the range of theories included in each reflects the disciplines involved or the contexts examined (Glanz and Rimmer 1997; Conner and Sparks 2005; Nutbeam et al. 2010; Michie et al. 2014). It also means that stakeholders (including the public) must be included in a process of co-creating interventions to ensure that their experiential knowledge of the problem and its context can be factored into the theory of change (Moore and Evans 2017).

Development of intervention logic models

Logic models are diagrammatic representations of the intervention theory of change and of the logical relationships, for example, between an intervention's inputs, activities, outputs, and outcomes, although there is scope for flexibility regarding the precise categories used (Cooksy et al. 2001; W.K. Kellogg Foundation 2004). Intervention theory and logic models are useful tools in clarifying how an intervention is to be delivered and to what ends, and thereby provide a focus for evaluating process (and outcomes). Figure 6.5.2 provides an example of a recent logic model. It is for the Learning Together (INCLUSIVE) intervention which was designed to reduce bullying and aggression in secondary schools (Bonell et al. 2018a). The intervention's theory of change is informed by Markham and Aveyard's theory of human functioning and school organization (Markham and Aveyard 2003). Its tenets inform a diagrammatic logic model consisting of inputs, processes, institutional changes, intermediate impacts, and health outcomes. Inputs include training staff in 'restorative practice' (RP) as an approach to preventing and managing student aggression and misbehaviour, as well as an external facilitator to convene meetings of students and staff to review data on student needs in order to plan and deliver school-specific

actions. These inputs are intended to enable processes, such as improved personal, social, and health education (PSHE) and the use of RP in schools, as well as the review and revision of school policies and rules by staff and students working collaboratively. In turn these processes are intended to modify various 'boundaries' within the school, such as the quality of staff–student relationships, and how schooling is framed, for example, to render decision-making more student-centred. These processes are ultimately theorized as transforming the ethos of the school so that more students use their sense of agency to commit to the school's instructional order (teaching) and the regulatory order (discipline and school sense of community) and are thus less likely to decide to commit to antischool peer groups and behaviours such as bullying and substance use which can function symbolically as alternative, antischool markers of identity and status.

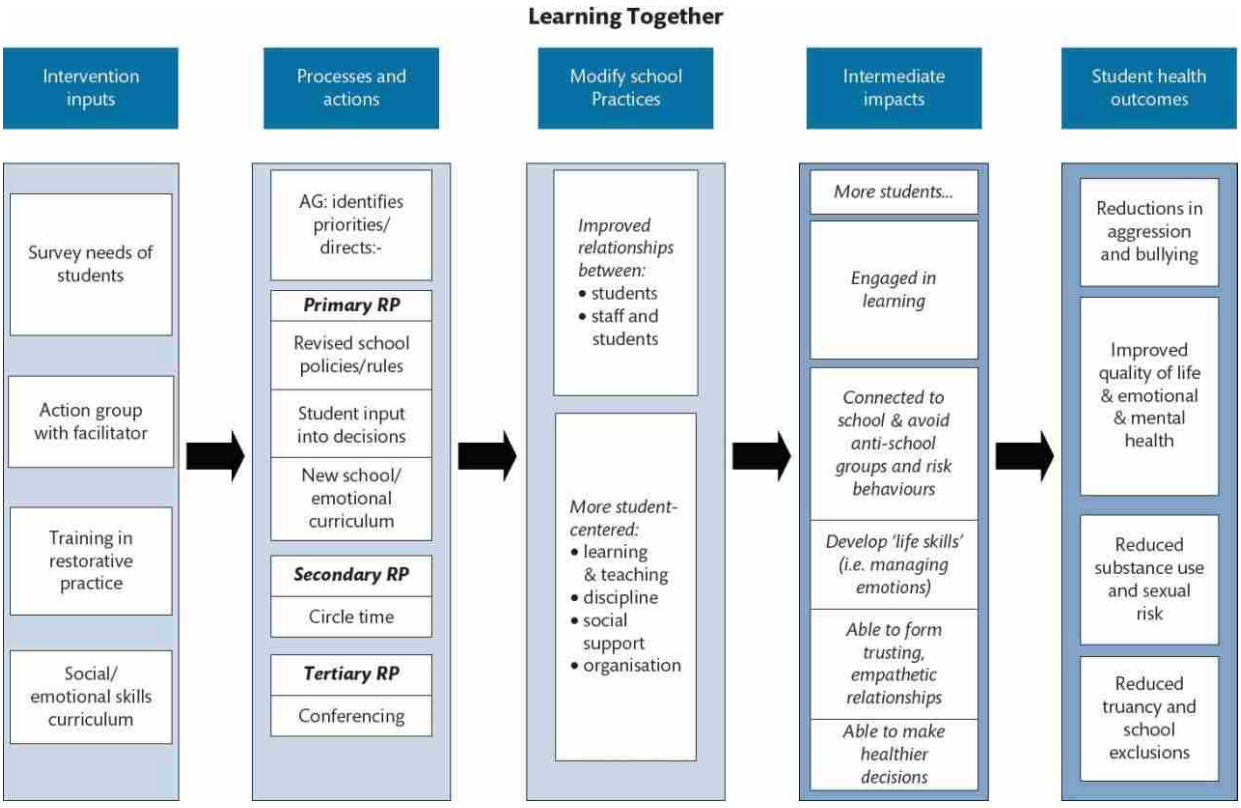

Fig. 6.5.2 Logic model for the Learning Together (INCLUSIVE) intervention.

The intervention has been tested in a cluster RCT in 40 secondary schools in England and was shown to have a modest, but in public health terms an

important, impact on bullying but no effect on aggression (Bonell et al. 2018a).

While useful, logic models have limitations. They describe linear chains of causation, offering no indications of how intervention implementation or the mechanisms by which outcomes are generated might interact with and therefore vary by context. In the case of INCLUSIVE, the linear logic model was augmented by additional context-mechanism-outcome (CMO) hypotheses suggesting how contextual factors and intervention mechanisms might interact to generate different outcomes in different settings. A further problem with logic models is that they can sometimes lead to the variables used to measure phenomena being confused with the phenomena themselves, thus reducing social, psychological, or biological mechanisms to chains of variables with little discussion of what processes connect these. So, while logic models provide a useful summary and guide to empirical assessment, they should build on a more nuanced textual description of the theory of change (Skivington et al. 2021). In the case of INCLUSIVE, for example, the theory of change invoked concepts such as agency to make decisions as well as the symbolic meaning of risk behaviours such as bullying, to explain intervention mechanisms (Bonell et al. 2018b).

Public health interventions, complex or otherwise, can also have unintended consequences and the potential to harm (Lorenc and Oliver 2014). Theorizing an intervention's potential iatrogenic mechanisms and harmful effects and developing so called 'dark logic' models to represent these ensures that they are considered in any evaluation with a view to understanding how they might be mitigated or avoided in future (Bonell et al. 2015b).

Evaluation of complex interventions

Piloting and feasibility studies

Before embarking on an RCT (or some other evaluation of the effects of a public health intervention), it is wise to undertake a pilot or feasibility study. Guidance on how to conduct these has been lacking but the main report from the GUEST study (Guidance for F**e**asibility Studies of Complex Public Health Interventions) will be published shortly (Moore et al. 2018). The terms pilot and feasibility study have tended to be used interchangeably

(Arain et al. 2010) but Eldridge and colleagues (Eldridge et al. 2016) suggest that a pilot study is just one form of feasibility study. A pilot study is in effect a miniature version of the main randomized trial (or whatever design is anticipated to examine effectiveness) and is designed to test that both the intervention and the evaluation can be implemented as intended. If the pilot is successful and no changes are made, then data from it can be incorporated into the main study (this is termed an internal pilot as opposed to an external one where data cannot be incorporated into the main study because the intervention or the evaluation methods are refined between pilot and main study). In contrast, feasibility studies are intended to examine specific, discrete areas of uncertainty to decide whether an effectiveness study is feasible or worthwhile, such as the willingness of participants to be randomized, response rates to questionnaires collecting outcome data, or the standard deviation of the primary outcome measure required for the sample size calculation. Feasibility studies also provide the opportunity to test out and optimize the intervention. Such studies need not pilot every aspect of a main study, including random allocation, and will use whatever methods are required to address the identified areas of uncertainty.

Setting predetermined criteria for progression from a feasibility study or a pilot trial to the main study of effectiveness helps bring objectivity to whether or not to proceed and may be required by research funders. Criteria may inform binary stop/go decisions or more nuanced red/green/amber with amber denoting progression contingent on some refinements. Next in Table 6.5.2 are the criteria set for progression to a full-scale RCT to test the cost-effectiveness of a secondary-school-based intervention to improve teacher well-being. Part of the intervention involved training a cadre of teachers in intervention schools in mental health first aid so that they could provide peer support to colleagues. Not all the criteria were met but the full trial was funded because the study authors successfully argued that what they had learnt in the feasibility study would enable them to improve the recruitment of schools and peer supporters, and increase questionnaire response rates from teachers.

Table 6.5.2 Criteria for progression from a pilot to a full RCT in the WISE (Wellbeing in Secondary Schools) Study and the outcome.

Criterion	Outcome
Recruit and maintain peer supporter teams assuming ratio of 1 peer supporter: 15 staff members	Mean ratio of 1 peer supporter: 17 staff members
50% schools willing to be recruited and randomized	Wrote to 33 eligible schools: 9 requested further information, 7 met with the research team, 6 took part in the feasibility study
Response rate of at least 75% in staff and student follow up questionnaires	Response rate at follow up 52.7% all staff (66.2% teachers) and 85.7% students
Average of at least one intervention a month delivered by each peer supporter	Mean of 3 people per supporter per 2 weeks BUT some supporters as many as 12 per 2 weeks, while others provided no support

(Kidger J. 2019, personal communication).

Process evaluation methods

Process evaluation is as important as outcome evaluation. Process evaluation can provide valuable insight not only within feasibility and pilot studies, but also within full RCTs as well as in studies examining implementation of scaled-up interventions after effectiveness trials have been completed. Process evaluations can examine how interventions are planned, delivered, and received (Bonell et al. 2006; Oakley et al. 2006).

There is no single, agreed definition of process evaluation. The UK MRC guidance on the subject states that a process evaluation 'is a study which aims to understand the functioning of an intervention, by examining implementation, mechanisms of impact, and contextual factors. Process evaluation is complementary to, but not a substitute for, high quality outcomes evaluation' (Moore et al. 2015). Other priority areas have been identified. One of the most widely cited frameworks is that of Steckler and Linnan (2002) which identified priority areas for process evaluation, including fidelity (the extent to which the intervention is delivered as intended), reach (whether an intervention is received by all those it targeted), dose delivered (the amount or number of units of intervention offered to

participants, dose received (the extent of participants' active engagement in the scheme), and context (local factors which impact implementation). Thus, process evaluation can explore whether those whom an intervention targets actively engage with it, an important consideration for social interventions. The following subsections consider some of these priority areas in more depth.

Intervention delivery and fidelity

The importance of process evaluation was increasingly recognized during the 1980s, informed by discussion of 'type 3 error', defined as concluding that an intervention is ineffective because of a failure of its theory of change when lack of effect reflects its not being implemented as intended (Basch et al. 1985). Initially, the main aim of process evaluations was therefore to assess intervention fidelity to determine whether outcomes evaluation could represent valid assessment of an intervention's underlying theory. Fidelity is defined variously. Moncher and Prinz (1991) define fidelity as confirmation that manipulation of the independent variable occurred as planned. Within the context of an RCT or other comparative evaluation, this requires assessment of the integrity of both delivery within the intervention arm and its differentiation from what occurred in the control arm. Later definitions of fidelity, for example, by Lichstein and colleagues (Lichstein et al. 1994) saw this as also encompassing receipt (participant uptake of the intervention) and enactment (the extent to which participants apply the lessons of interventions into practice in their lives). But such definitions begin to blur the useful distinction between fidelity and factors such as dose, acceptability, and even outcomes, so most researchers continue to define fidelity more narrowly in terms of delivery.

Assessments of fidelity generally involve quantitative measurement, for example, using observations, video-recording, or provider self-assessments to audit delivery against what was intended. However, fidelity should not be viewed only in terms of ticking boxes on simple checklists. Steckler and Linnan (2002) argue that when evaluating fidelity, it is also important to assess whether the 'spirit' of an intervention is delivered in practice, and not just its mechanics. For example, when evaluating motivational interviewing, which is counselling aimed at enabling clients to recognize their own motivations for behaviour and to modify behaviour where this is not in line

with their own goals, it is important to evaluate fidelity not merely as a cookbook list of techniques, but also whether the underlying empathic, patient-centred spirit of the approach is achieved (Miller and Rollnick 2009).

Another important consideration when evaluating fidelity is the degree to which interventions should be standardized. Advocates of strict fidelity (Mihalic 2004) argue that this is essential if effective interventions are to be replicated, especially when an intervention's 'active ingredient' may not be known (or is thought to arise from synergies between all components). They present evidence which suggests that high fidelity is associated with greater impact for some interventions (Mihalic 2004). In contrast, advocates of local adaptation (Dane and Schneider 1998) argue that interventions need to be tailored to local circumstances. Durlak and DuPre (2008) propose a compromise whereby an intervention's 'core components' should be delivered in standard form but less central intervention components or features can be modified to fit local needs. They present research suggesting that a balance between fidelity and adaptation is likely to be most effective, with the precise balance dependent on the specific intervention. As noted earlier in this chapter, Hawe and colleagues go further to argue that with complex interventions characterized by interactions between multiple components and between intervention and context, too much attention has been paid to standardizing the *form* of intervention components (what precise actions are delivered) and more attention should be given to standardizing the *function* of intervention components (what the aim of each component is and how it contributes to the overall aim of the intervention) (Hawe et al. 2004). Consider the case of the INCLUSIVE intervention described earlier. Fidelity of form might be measured by determining whether the training in RP was delivered as planned and whether the facilitator convened a sufficient number of staff–student meetings. In contrast, fidelity of function might be measured by determining whether teachers were equipped to deliver RP and whether staff and students felt involved in the process of reviewing school policies.

Intervention reach, dose, and acceptability

Steckler and Linnan conceive of evaluating intervention reach and dose, and participants' responses to an intervention largely in quantitative terms (Steckler and Linnan 2002). Reach and dose are commonly examined

quantitatively using methods such as questionnaire surveys exploring participants' exposure to and satisfaction with an intervention. However, receipt can also be seen in qualitative terms as exploring participants' reports of an intervention in their own terms. Qualitative research can be useful in examining how participants perceive an intervention in unexpected ways which may not be fully captured by researcher-developed quantitative constructs. Qualitative research can also explore how providers or participants enact 'agency' (willed action) in engaging with the intervention rather than merely receiving it passively (Oakley et al. 2006). For example, process evaluation of a youth work intervention to reduce teenage pregnancy in England reported how some youth workers and teachers responded to onerous recruitment and retention targets by transforming the intervention from one delivered out of school hours to one delivered as a partial alternative to normal school time, which may have explained its ineffectiveness (Wiggins et al. 2006).

Context

Context is a critical aspect of process evaluation. Although there is no consistent definition (Craig et al. 2018) context can be taken to mean anything that was in place before the intervention itself was implemented. This could include factors such as the needs of participants, the infrastructure within which interventions will be delivered, the skills and attitudes of providers, and the attitudes and cultural norms of potential participants. In Steckler and Linnan's (2002) framework, context is largely considered in terms of factors which may help or hinder implementation. For example, an intervention may be delivered poorly in some areas, but well in others, because of better provider capacity or more receptive community norms in some areas. Others consider context also in terms of how it influences outcomes. For example, 'realist' evaluators place great emphasis on whether intervention mechanisms generate beneficial outcomes in some contexts more than others. Context can be measured quantitatively in order to inform 'moderator' analyses within or between trials, though the latter is rarer (Bonell et al. 2012). Qualitative research allows for a different understanding of the importance of context, for example, examining how intervention providers or recipients describe the interaction between their

context and their own agency in explaining their actions (Oakley et al. 2006).

Intervention mechanism of action

Assessing an intervention's mechanisms of effects involves assessing the validity of the theory of change in explaining how outcomes are generated. Such analysis can explain why an intervention is found to be effective or ineffective within an outcome evaluation. This might be critically important in refining an intervention found to be ineffective or in understanding the potential generalizability of interventions found to be effective. Quantitative data can be used to undertake mediator analyses to assess whether intervention outputs or proximal outcomes appear to fully or partially account for intervention effects on distal health outcomes (Gardner et al. 2006). Qualitative data can be also used to examine such pathways in terms of how they are perceived and described by those involved, and this is particularly useful when the pathways in question have not been comprehensively examined using quantitative data, as well as when pathways are too complex (e.g. using multiple steps or feedback loops) to be assessed adequately using quantitative analyses. This was, for example, the case with an assessment of possible causal pathways underlying an intervention to modify school environments in order to reduce student substance use, which appeared to involve feedback loops whereby student participation within certain intervention activities increased student commitment to the intervention which in turn increased student participation within other components (Bonell et al. 2010).

However, such analyses can be challenging. First, as suggested earlier, quantitative analyses require evaluators to have correctly anticipated what data are needed to examine causal pathways and to have collected these. For example, the evaluation of the youth work intervention aiming to prevent teenage pregnancy reported a higher rate of pregnancies among those receiving the intervention. It was hypothesized that this apparent adverse outcome resulted from the intervention bringing together young people engaged in risk behaviours so that pro-risk social norms were amplified. However, data on these were not collected so that this hypothesis could not be tested (Wiggins et al. 2008). A second challenge involves using qualitative alongside quantitative data to understand causal pathways. If

qualitative data are analysed in order to explain quantitative findings, this may bias interpretation (Wight and Obasi 2002; Campbell et al. 2015). Furthermore, quantitative and qualitative methods originate from different research traditions. Qualitative research focuses on participants' accounts, drawing out generalizations about meanings and agency using largely inductive methods. They offer rich insights into how actors understand social phenomena rather than trying to test hypotheses about causal associations. As Munro and Bloor (2010) put it: 'process evaluations do indeed enrich our understanding of the social processes involved in the delivery and receipt of complex interventions', they provide 'interpretations to which a degree of indeterminacy is always attached that cannot be expressed in probabilistic terms. The continuing tension between positivist and interpretive paradigms within that research design pose problems of understanding and reporting. Not so much "paradigm peace" as "paradigm truce" '.

While we advocate process evaluation as an important evaluative tool it should not be seen as a panacea for answering all the questions an outcome evaluation cannot, nor is its use unproblematic. The range of possible domains it can focus on (delivery, fidelity, reach, dose, acceptability, context, sustainability) is wide, and resources may not be available to collect the data required to examine them all. Some may be a greater priority than others depending on the nature of the intervention and its stage of development. For example, the acceptability of an intervention is something that should predominantly be explored in a pilot or feasibility study rather than leaving it till the definitive trial, where understanding mechanism of effects may be a more pressing matter for a process evaluation to examine.

Implementation issues

Sustainability

The implementability and sustainability of new public health interventions at a scale capable of population impact is an important consideration. For example, it may be that a group of health promotion specialists, substance misuse experts and youth workers have been specially assembled to deliver a new intervention in secondary schools to reduce substance and alcohol misuse. This intervention is shown in a cluster RCT to be effective. The

issue then becomes how can that delivery model be replicated and sustained outside of the trial so that effectiveness is maintained. The 'RE-AIM' framework (reach, effectiveness, adoption, implementation, maintenance) is useful in conceptualizing this (Glasgow et al. 1999). Its originators argue that those commissioning public health services need to know not only that an intervention is effective but that it is capable of being adopted by provider agencies and implemented by them as planned, and will reach sufficient people to achieve a population health impact that can be maintained over time (Glasgow et al. 2001).

From research into practice

The impact of research on policy and practice is increasingly recognized to occur through a gradual and indirect process of enlightenment rather than via direct effects of single studies or even reviews on single decisions (Weiss 1986; Graham et al. 2006). However, while empirically accurate, this is normatively disappointing for those advocating a more direct role for evidence in informing policy (Davies et al. 2000). Now there is recognition that to be influential, research needs to engage reciprocally with policy and practice. Earlier in this chapter we highlighted the need to consult key policy and practice stakeholders and the public early in the development and evaluation of complex public health interventions. This approach is now being extended by some into a process whereby evidence is co-produced through a knowledge exchange partnership between researchers, policymakers, and practitioners using transdisciplinary action research (Daker-White et al. 2014). This method involves academics from a variety of relevant disciplines working with policymakers, practitioners, and the public to identify what research is required, develop research questions, conduct evaluations, synthesize evidence, and implement and maintain evidence-based public health practice. The advantage of this approach is that if evaluations indicate that changes to practice are producing the desired outcomes then the capacity-building necessary to sustain that whole system change is built into the approach. There are a number of examples of promising interventions (de Silva-Sanigorski et al. 2010; Chittleborough et al. 2013), including the INCLUSIVE intervention in England (Bonell et al. 2015a; Bonell et al. 2018a) and the Gatehouse project in Australia, where this approach has been taken (Bond et al. 2001, 2004).

Discussion and future direction

Public health interventions can comprise policy-level initiatives implemented at a national or international level, for example the World Health Organization's Healthy Cities programme (World Health Organization, n.d.), through to brief individual behaviour change interventions to encourage reduced alcohol consumption delivered in primary care populations (Kaner et al. 2007). Interventions may be programmatic in nature with many different components such as Project Northland in secondary schools to reduce alcohol consumption, or it may be simpler, as in the example of human papilloma virus vaccination which involves three injections over a 12-month period to reduce substantially the chances of a woman having cervical cancer. Given this huge variability there is no 'one-size-fits-all' approach to their development and evaluation. What we have identified in this chapter are the key issues to be considered and the range of methods available to tackle them.

We conceive of the development and evaluation of complex public health interventions as distinct elements but ideally part of an overall symbiotic and cyclical process rather than sequential phases. Knowledge exchange partnerships between researchers and public health practitioners and policymakers offer a way of achieving this ideal, but, as is sometimes the case with the interventions themselves, the evidence suggests that the effectiveness of knowledge translation varies according to context (LaRocca et al. 2012).

Economic appraisal in public healthcare: assessing efficiency and equity

David Parkin, Stephen Morris, and Nancy Devlin

What is economic appraisal?

Planning healthcare services to meet the health needs of a population must always recognize that availability of resources with which to meet them is a constraint on the achievement of its goals. There are many choices that must be made reflecting that constraint. For example, which public health and healthcare services should be provided, how they will be provided, and to whom they will be provided. Economic appraisal (EA) is a systematic way of analysing the consequences of such choices. It is one element of health technology assessment (HTA), the uses of which include among other things healthcare pricing and reimbursement decisions, planning the location of healthcare facilities, and setting of priorities for confronting health problems. EA is not the only element of HTA, but it is an important one.

Similarly, the discipline of economics is not the only contributor to EA. It also requires other public health relevant disciplines such as epidemiology, statistics, and operational research. Economics contributes the rationale for EA, an overall framework for analysis, and some measurement principles and methods.

The term ‘economic appraisal’ describes a set of techniques that weigh up the costs of an action, such as providing a particular type of healthcare to a patient or demographic group, against the benefits that it provides. The term ‘economic evaluation’ is also used. The distinction between these terms is that appraisal is undertaken before the action is taken, to help in deciding whether or not and how the action is to be done, and evaluation is undertaken after the action, to judge its effects. This distinction is often forgotten, and these terms are used interchangeably in much of health

economics. The expression ‘evaluation’ is now most commonly used in the health economics literature, but appraisal is used here because that more accurately describes the main purpose for which economic analysis in healthcare is applied in practice. The usual label given to this activity in economics is cost-benefit analysis (CBA). However, that term is often reserved in healthcare EA for a particular technique, which is explained later in this chapter.

The principles of EA can be applied to all kinds of health interventions, from individual patients’ treatments to population-based programmes, all of which may be of interest to public health practitioners. This chapter therefore does not restrict itself to activities conventionally labelled as public health, and also includes interventions that are not usually thought of as healthcare, such as health promotion. It highlights the special issues that EA faces in evaluating public health activities and finishes with a specific examination of those issues.

The economics of economic appraisal

EA should not be confused with *financial* appraisal. A financial appraisal is concerned with the monetary implications of a proposed action, such as investment in a healthcare facility or the provision to a population of one or more interventions. It examines cash expenditures and available funding to ensure that the actions taken are viable and provide a reasonable return. These cash flows are measured using accounting principles. EA shares some of the methods and principles of financial appraisal, but its aim is a more general assessment of costs and benefits and has measurement principles derived from economics concepts. The most important of these are *opportunity cost*, *social cost*, *marginal cost*, *efficiency*, and *equity*.

In practice, these theoretical principles are hard and occasionally impossible to adhere to, but they provide a guide as to the best sources of cost and benefit data and to the reliability of the numbers used.

Opportunity cost

As with any goods and services that are created within an economy, production of healthcare requires resources such as personnel (often referred to as labour), equipment and buildings (often referred to as capital), land,

and raw materials. There are finite amounts of such resources available to be converted into goods and services at any particular time, so it is not possible to produce everything that everyone in a population might want. Resources are therefore scarce relative to the demands for them. In the economy as a whole, there are not enough scarce resources to meet all of the wants that people have, so we have to choose which wants are met and which are not met. Similarly, in the healthcare system there are not enough healthcare resources to meet all of the health needs that people have, so we have to choose which needs are met and which are not met. Of course, it might be argued that if we cannot meet all health needs, resources should be diverted from other parts of the economy, and it is legitimate for public health practitioners to advocate that. But it would not be possible to do that indefinitely, and the consequences might be a reduction in education, welfare, and other goods and services in the public and private sectors of the economy that are not only desirable in themselves, but also contribute to maintaining and improving the health of the population.

Economics claims that scarcity and the resulting necessity to choose are ubiquitous and unavoidable. This leads directly to an important and fundamental economics concept, *opportunity cost*. If scarce resources are used to produce a good or service, those resources cannot be used to produce other goods or services. There is a lost opportunity to enjoy the benefits that those other goods or services would have provided. Because there are many possible uses for resources, the opportunity cost of using resources in a particular way is defined as the benefits that would have resulted from their *best* alternative use.

When economists refer to costs, they usually mean opportunity costs. This is quite different to the more familiar concept of financial costs, the costs of goods and services and of scarce resources in terms of money. Very often, financial costs are used to measure opportunity costs, but this is not always the case. Opportunity costs and financial costs are different ways of thinking about costs, rather than separate elements of overall costs; it would make no sense to calculate them separately and add them together, for example.

Measuring opportunity costs is often difficult in practice. It is preserved in good EA practice by the separation of costing services into measuring the quantity of resources required to provide that service and calculating the value of those resources, by, for example, examining the prices of each type of resources. This is also good practice for ensuring that research can be

generalized to other settings where quantities and prices may differ. For example, different countries may have very different ways of providing services, with different combinations of different kinds of personnel, facilities, and locations, as well as differing relative costs of those resources.

Social costs and benefits

A financial appraisal of a proposed action takes into account only costs that are incurred by the person or organization taking the action and benefits to the person or those who are the organizations' clients. These are referred to as private costs and benefits. However, in some kinds of EA it is in principle essential to take account of all costs and benefits to society, whatever they are, and whoever incurs them. In particular, it is essential to take account of *social costs and benefits* in a CBA that examines the impact of the action on the economy as a whole. For example, the total costs of a medical intervention would include not only costs incurred within the health sector, but also those incurred in subsequent personal care and support, whether by organizations or private carers. However, it is arguable that such wider costs should not be included for some of the EA methods discussed next, for example, in a cost-effectiveness analysis (CEA), in which the aim is to maximize healthcare outcomes within a limited budget.

A special example of the difficulties involved in this is accounting for *transfer payments*, examples of which are social security payments and other state benefits paid out of taxation. Except for the costs involved in administering them, these are not costs to society as a whole. Rather, they are transfers between different members of society, since the recipients derive benefits from them that match the costs to taxpayers. However, from the state's point of view such expenditure may be regarded as a use of tax revenues which has an opportunity cost in terms of other government expenditure.

Again, the principle of including all social costs and benefits is almost impossible to follow perfectly because of information limitations. However, it is preserved in good practice in health EA by identifying costs and benefits according to who bears them, in three categories: the health service, patients and their families, and the rest of society. It is also embodied in the recommendation that any analysis should make clear the perspective from

which the analysis is conducted, for example, society, the government, or the health sector.

Walker et al. (2019) have argued that adoption of an abstract 'social perspective' is not helpful in undertaking EA in practice and have developed a framework by which these issues can be considered in a systematic way. This is further discussed next in the context of EA of Public Health interventions, where it is of special importance.

Marginal costs and benefits

The total cost of any activity will depend on how much of it is carried out. For example, the total cost of a vaccination scheme will depend on the number of people to be vaccinated. If the total cost of the activity and the number of units of activity are known, it is possible to calculate an average cost per unit of activity, which is what accounting data usually provide. However, in some circumstances average costs may be a misleading estimate of the cost of a unit of activity, and what are required are *marginal costs*.

Marginal cost is the change in cost that is caused by the smallest possible change in another variable to which it is related. The marginal cost of a good or service is usually more specifically defined as the extra cost incurred in producing one more unit of it. Note that marginal does not mean small or unimportant; instead it means at the margins of an existing condition, for example, the cost that will be incurred by changing the allocation of resources slightly. That cost could actually be large, even though the change in the amount of the good or service is small. As an extreme example, suppose that the service is a screening programme and the screening centre processing the test material has reached full capacity. Screening an extra person could only be carried out if a new screening centre was built, so its marginal cost would be very high. By contrast, the marginal cost of the last test performed within the existing capacity may have been quite small, simply the cost of performing the test. This demonstrates another important point. Marginal cost may vary considerably with respect to the same size of change in the other variable, depending on the level of that other variable, in this case the number of people screened.

An example of the importance of looking at marginal costs is the impact of schemes designed to lower hospital inpatient surgical costs by reducing length of stay through earlier discharge. Hospitals may have information on

the average cost of an inpatient stay, which can be used to calculate an average cost per day. However, the costs of an inpatient day are not constant. In particular, they may be much smaller than the average towards the end of the stay, because the average includes a share of the costs of treatment and perhaps of high dependency care that took place towards the beginning of an inpatient stay. So, reducing the number of low dependency days at the end of the stay will save far fewer resources than would be expected by examining the average. Marginal costs calculated with respect to an increase or decrease in the number of days would give a correct estimate of the likely savings.

The same principles apply to benefits. Marginal benefits are the extra benefits obtained by consuming one more unit of a good or service. An example of the importance of looking at marginal rather than average benefits is a screening programme that can be carried out with different numbers of sequential tests. The more tests, the more cases are detected. A programme that used two sequential tests might yield 11 cases per 10,000 people tested, which could look reasonable. But suppose that a programme that used only one test would discover ten cases. The marginal benefit of including the second test is only one case per 10,000, which does not look so good.

To give a real example, Torgerson and Spencer (1996) illustrated the importance of marginal analysis by analysing data on the cost-effectiveness of biochemical screening for Down's syndrome as a replacement for screening by maternal age. An estimate had been published that introducing biochemical screening in a population of 20,000 pregnant women would cost £413,501 and might prevent 11 affected births, giving a cost-effectiveness ratio of £37,591 per affected foetus identified. Torgerson and Spencer pointed out that for the same number of women, existing antenatal screening procedures based on maternal age and additional tests already cost £79,500 with four births potentially prevented. So, the true cost-effectiveness of biochemical screening was (£413,500—£79,000)/(11–4) = £334,500/7 = £47,786, a much higher cost per affected foetus identified than for the estimate based on average cost.

Efficiency and equity

Economic analysis is usually employed to judge the way in which scarce resources are employed according to two main criteria: efficiency and equity. These two concepts have technical definitions, which will be described in the following subsections, but in very broad terms efficiency refers to obtaining the greatest output for a given set of resources and equity refers to a fair distribution of that output among the population. The term 'output' is very general and in our context we usually mean the additional amount of healthcare or health produced.

Efficiency

It is necessary to give a warning about definitions of efficiency. Economists, as specialists in the analysis of efficiency, largely agree about what it means and how different types of efficiency may be defined, but the labels they give to those types vary. The same concept may be given to different names and the same name given to different concepts. Here we use the labels and definitions given in Morris et al. (2012).

Knapp (1984) gave a very broad definition of efficiency as 'the allocation of scarce resources that maximizes the achievement of aims'. This is a useful start, because it suggests the benign nature of the desire to achieve efficiency. If we have scarce resources and competing uses for them, our aim will be to obtain the best set of uses, with 'best' defined in whatever way we want. If we decide that the aim of the health system is to improve the health of the population and we have a fixed healthcare budget, we will obtain the biggest health gain if the allocation of scarce healthcare resources is efficient.

For practical purposes, we require more precise and technical definitions of efficiency. However, it is useful first to understand a slightly abstract idea, called *Pareto efficiency* which is also, though not consistently, called *allocative efficiency*. This arises from an attempt to create a widely acceptable criterion for judging different allocations of resources to different ends. The suggestion is that we would be able to say that one allocation is better than another if at least one person is better off under the first allocation and no one is worse off. This is called the *Pareto criterion*. Consider a change from one allocation of resources to another, for example making changes to the kind of care that is made available in the healthcare system. If some people benefit and no one is made worse off, this is described as a *Pareto improvement*. If it is not possible to make any such

changes, then we have achieved a *Pareto optimum*. Another way to view the Pareto optimum is that it is a position where it is not possible to make anyone better off without making someone else worse off.

If we aim to make people as well off as possible and are not concerned about whether some people are better off than others, then a Pareto optimum is efficient. We cannot further improve the achievement of our aim because even if we can make someone, or even many people, better off, we do not know if this is outweighed by those who are made worse off. This is not a unique position; there are many allocations of resources that would be Pareto optimal, some of which would imply great inequalities between different people. If our aims also took account of the undesirability of inequalities, then we might not view all Pareto optimums as efficient. Nevertheless, ideas of efficiency in economics derive from this concept of Pareto efficiency. Here, we define three types: *technical*, *economic*, and *social*.

Technical efficiency is a concept that is used in considering how health and healthcare, or 'outputs', are produced from scarce resources, or 'inputs'. There is technically efficient production if the most output possible is being produced from a given amount of inputs or the fewest possible inputs are used to produce a given amount of output. For example, the number of people that can be vaccinated against influenza in a general practice clinic depends on the number of nursing staff that are available and other inputs. If the most that can be provided by three practice nurses is 100 vaccinations each day, then it is technically inefficient if 99 vaccinations are provided by three nurses or 100 vaccinations by more than three nurses.

Another way of viewing technical efficiency, which is consistent with Pareto efficiency, is that the practice cannot vaccinate more people without employing at least one more nurse. More generally, production is technically efficient for a given set of inputs if it is only possible to produce more by employing more of at least one input.

In practice, EA does not directly address technical efficiency, though as will be explained it is an essential underlying assumption in most cases.

Economic efficiency is given different labels, including cost-effectiveness, though that term should be used carefully, as will be explained next. Technical efficiency is defined with respect to the physical numbers of inputs, but economic efficiency is interested in the cost of those inputs. Economic efficiency is achieved if we are producing most output for a given cost or producing a set amount of output at the lowest possible cost. Using

the earlier example, suppose that people could be vaccinated by different grades of nurses, but at least one senior nurse must be part of the team. It might be equally technically efficient for 100 people to be vaccinated each day by employing one senior and two junior nurses, one junior and two senior nurses, or three senior nurses. But senior nurses are more expensive to employ than junior nurses, so it will be economically efficient to use the first of these staff mixes. This demonstrates that although achieving technical efficiency is necessary to achieve economic efficiency, not all technically efficient ways of producing are economically efficient.

Another way of viewing economic efficiency, which is consistent with Pareto efficiency, is that given the costs of employing nursing staff, the practice cannot undertake more treatments without them costing more to provide. More generally, production is economically efficient for a given set of input prices if it is only possible to produce more by incurring greater costs.

In practice, economic efficiency is the dominant type of efficiency analysed in EA. However, there are different ways in which this is done, as will be explained next.

Social efficiency is a much broader concept than technical and economic efficiency. If there is economic efficiency in production in every part of the economy, there is allocative efficiency in production for the economy as a whole. There is an equivalent concept relating to the consumption of goods and services called allocative efficiency in consumption where, given prices of goods and services, consumers maximize the benefit that they derive from those goods and services. If both of these are achieved, then there is allocative efficiency in the economy as a whole, which is also known as social efficiency. This is the same as the Pareto efficiency described earlier.

Obviously, social efficiency according to this strict definition is not a concept likely to be of practical use in health economics. However, it is important because it underlies CBA, whose aim in theory is to move the economy closer to social efficiency.

Equity

Equity is an important criterion for allocation of resources, and it is particularly important in health systems because it is observable that people attach more importance to fairness in health and healthcare than to the distribution of many other goods and services. Almost every healthcare

system in the world has equity as an important policy objective. However, economic analysis of equity is less clear than that of efficiency, except for how equity might be measured, and there is less agreement among economists about it.

Equity means fairness, and in the context of healthcare this means fairness in the distribution of health and healthcare between people and in the burden of financing healthcare. It is not a synonym for equality, which means an equal distribution. It may not always be fair to be equal, for example, it might be thought to be unfair if both healthy and sick people are given the same amount of healthcare. But equality is often used to define equity, as, for example, in the principles of horizontal equity—equal treatment of those who are equal—and vertical equity—unequal treatment of those who are not equal. An example often used in healthcare is the proposal that there should be equal access to healthcare for people with the same level of healthcare needs.

That is not the only possible definition of healthcare equity, and more generally there is no single definition of what equity is. Moreover, ideas about equity are not mainly founded on economics principles, rather on philosophy, ethics, law, and other forms of enquiry. An example is the equity principle of procedural justice, which in this context might mean that the process used to decide on the allocation of healthcare resources between people should be fair. This is an important principle in deciding how HTA is applied, but it is not especially based in economics. Culyer and Bombard (2012) have suggested that one way to incorporate the plurality of approaches to equity in HTA is to use a ‘checklist’ to ensure that decision-makers take all aspects into account.

Cookson et al. (2017) have developed a framework for examining both equity and efficiency, in terms of cost-effectiveness, in a systematic and consistent way. It uses two analytical concepts, *health equity trade-offs* and *net equity impacts*. It uses these to describe two approaches to conducting cost-effectiveness analyses that incorporate equity concerns, *equity impact analysis*, and *equity trade-off analysis*, which are described next.

Health equity trade-offs result from the possibility that efficiency and equity may conflict under some circumstances. For example, a screening programme may be cost-effective in terms of the cost of detecting treatable cases, leading to an overall increase in health for the population as a whole, but if take-up is lower among groups who have worse overall health, this

will lead to a widening of health inequalities. There are therefore four possibilities, as in Table 6.6.1:

Table 6.6.1 Health equity trade-offs

		Net health impact	
Positive	**Negative**		
Health equity impact	Positive	1 Cost-effective Improves equity	4 Cost-ineffective Improves equity
	Negative	2 Cost-effective Harms equity	3 Cost-ineffective Harms equity

The suggestion is that healthcare that falls into box 1 should be pursued and those that fall into box 3 should be avoided. There is however a trade-off for healthcare in boxes 2 and 4 that should be explicitly considered by decision-makers.

Net equity impacts are based on the fact that the resources used in healthcare have opportunity costs. A healthcare intervention will generate a distribution of benefits between different groups and individuals within the population. However, alternative uses of the resources used by the intervention will also have benefits that are distributed within the population. Both of these must be considered in giving a full account of the impact of the intervention on equity.

It is necessary to consider what it is that we wish to be equitable about. Three areas in which equity may be considered are the finance of healthcare, the distribution of healthcare, and the distribution of health.

Analysis of equity in the finance of healthcare mainly concentrates on vertical equity, with a particular emphasis on whether or not healthcare is financed according to people's ability to pay. Horizontal equity in financing considers whether or not people, who have the same income, and therefore the same ability to pay for healthcare, make the same payments.

Horizontal equity in the distribution of healthcare mainly examines whether or not people with the same need for healthcare make the same use

of healthcare services. Vertical equity in the distribution of healthcare is usually interpreted to mean whether individuals with different levels of ill-health have different levels of use that are appropriate to that difference.

Equity in the distribution of health is almost always expressed in terms of inequalities in health. Health inequalities, particularly those that demonstrate that health levels vary systematically and inversely with socioeconomic status, are always of some importance in health policy debates and a major concern of some governments, depending on their political preferences. It may be argued that this is in fact the only real equity concern, since a concern for equity in healthcare derives solely from a concern about the distribution of health.

Formulating an economic appraisal

One way to look at how an appraisal is carried out is to consider it as a process with stages, as follows:

Defining the problem to be analysed. The problem is always the starting point of an appraisal. This may seem obvious, but in fact it is often solutions that are, wrongly, regarded as the starting point. From an appraisal point of view, the problem is not whether a fluoridation programme is cost-effective, but what the most cost-effective way is to deal with the problem of dental caries.

Specifying the alternatives. These are different ways of dealing with the problem defined in the first stage. It is important to select the most relevant alternative whatever it is, for example, promotion of tooth-friendly nutrition among children, or doing nothing.

Assessing costs and benefits which has three elements:

- Enumeration of costs and benefits, which means the drawing up of a descriptive list of the costs and benefits that are to be included in the appraisal.
- Measurement, which means obtaining data to describe the levels of costs and benefits for the different alternatives.
- Valuation, which is required to convert the data into values. For example, data on resource use should be converted into costs by applying to those data the value of the resources.

Calculating results means combining the data on costs and benefits into the results that will be presented. The exact nature of this will depend on the type of appraisal that is carried out and how uncertainty over the results is dealt with.

Deciding. The endpoint is when a decision is taken on the basis of the appraisal. This will not be taken by an appraiser, but by someone who has the responsibility to decide. However, appraisers often do recommend a decision which is based on their own appraisal or imply such a recommendation. This is legitimate if the relevant decision rules are known. For example, there might be an accepted decision rule that states that if the benefits of a health intervention exceed its cost then it should be provided to the population. A finding, for a particular intervention, that its benefits did exceed its costs may then lead to a recommendation that it should be provided.

One important factor in this is that an appraisal should be formulated and carried out with full awareness of which viewpoint is being taken. This arises because different actors in the health system—patients, health

professionals, and government, for example—may have different interests and concerns, so that what is efficient from one point of view may not be from another. This is important because it determines which type of appraisal is to be used, what constitutes a benefit and a cost, and how these are to be valued. Most appraisals will take the viewpoint of the health service, since that embodies most of those who have the legitimacy to decide which healthcare is to be provided. However, they may also take the viewpoint of society as a whole, since that defines the recipients of healthcare as well as the ultimate funders of it. Whatever viewpoint is adopted, researchers should be explicit about which it is. In EAs of public health interventions, a broader perspective is frequently taken, to account for costs and benefits that occur outside the health system.

Types of economic appraisal

Although there are several different types of EA, we will concentrate here on those most likely to be encountered in healthcare and other public health activities. Unfortunately, there are different ways in which these types can be classified. This leads to occasional disputes about how results of a particular type of appraisal should be interpreted or used. One way is to classify them according to what kind of efficiency they analyse. A second way is to classify them according to which costs and benefits are measured and how this is done. A third way is to classify them according to the type of decision that they apply to. Although we will discuss all three types here, the most widespread and popular classification in health economics is given by Drummond et al. (2005), which uses both the measurement and decision-type principles.

In what follows, we refer to what is being appraised as alternatives, reflecting the use of EA in healthcare in decision-making about alternative ways of using healthcare resources. This includes many kinds of decisions, including different ways of delivering healthcare, different types of healthcare, and different treatment options.

All of the types of EA discussed here are concerned only with the appraisal of efficiency. Variants of these that also assess equity are discussed in a separate section next.

Cost-benefit analysis

In economics more generally, CBA starts with an inventory of all of the costs and benefits of each of the alternatives, whatever they are, and whoever incurs them. This can be regarded as a balance sheet in which costs and benefits are weighed up against each other.

However, in healthcare appraisals CBA is usually defined, following Drummond et al. (2005), as a technique in which all costs and benefits are measured in terms of money. The rationale for this is that it is only possible to weigh up all of the costs and benefits if they are measured in the same unit. Although in principle any common unit could be used, in practice money is the obvious and natural choice, as it is the measure of value most used in modern economies. The result of such a CBA would be to establish which of the alternatives has the greatest net benefit, the difference between benefits and costs, which could of course be negative.

The main decision rule for CBA is that an activity should be undertaken if the sum of the benefits is greater than the sum of the costs or, identically, if the net benefit is positive. If only one activity with a positive net benefit can be undertaken (because, for example, there are limited funds), then the rule is to choose the activity with the highest net benefit.

CBA is based on economics theory, because if all of the costs and benefits are measured in the correct way—for example, all costs measure their true opportunity costs—and an alternative has a net benefit, it will lead to a Pareto improvement. The way that this has been interpreted by Drummond et al. (2005) is that CBA is therefore appropriate for answering questions about whether or not a healthcare programme should be implemented, or a treatment should be used, rather than which of a number of alternative programmes or interventions is the most efficient.

Because CBA requires benefits to be measured in financial or monetary terms and to cover a very wide range of costs and benefits, it is rarely used. An example in public health is Wang et al. (2005), who estimated a limited range of costs and benefits of using bike and pedestrian trails to reduce healthcare costs arising from inactivity. They calculated that the annual cost per person of using the trails was US$209.28 and the resulting reduction in medical costs was $564.41. This gives a net benefit of $355.13 per person.

Investment appraisal

Investment appraisal in the context of healthcare can be explained using the example of a specific technique called by the United Kingdom's finance ministry (the Treasury) option appraisal. This is described in the guidance that it gives to public bodies about how they should appraise and evaluate projects that are to be paid for from public funds; the distinction between appraisal and evaluation is carefully kept to in this case. It is a process in which different options for meeting an objective, defined by the aim of meeting some public need, are generated; CBA is applied to these options; and the best solution for meeting the aims is chosen on the basis of the results. For example, an appraisal of a project for setting up a new national programme for measuring obesity among schoolchildren would not start as a comparison of the new programme with the existing circumstances. It would start with the need to understand the extent of obesity among schoolchildren, generate different options for dealing with that need, which might include a new measurement programme, examine the costs and benefits of each alternative, and from this derive the economic case for the new programme, if it was found to be the best alternative. The economic case for the project would simply be part of a more general project appraisal including affordability and achievability and various types of impact assessment including on health, the environment, and health and safety.

Cost-consequences analysis

Cost-consequences analysis (CCA) is a form of CBA which does not try to put all of the costs and benefits into the same units. In particular, it accepts that there are different types of benefits that cannot be measured in the same units. This distinguishes it from CEA, which is discussed in the following subsection. The assumption is that in making decisions based on a CCA, different decision-makers will place their own weights on the different benefits and on costs, implicitly if not explicitly. CCA is of particular interest in public health because it is argued that it is more suitable for population health issues involving a wide range of agencies and of differing and incommensurable outcome indictors. For example, the National Institute for Health and Care Excellence (NICE) in England permits CCA to be used for public health interventions, unlike other healthcare. CCA is often referred to as a disaggregated approach, because the benefits and costs are

not combined into a single indicator such as net benefit or a cost-effectiveness ratio, which are defined next.

Cost-effectiveness analysis

Cost-effectiveness derives from the analysis of economic efficiency, where one alternative is preferred to another if it provides greater benefit at the same or lower cost, or lower cost for the same or greater benefit. This definition leaves open the question of which of two alternatives is more efficient if one provides greater benefit than the other, but at a lower cost. However, under certain conditions, for example, that the alternatives can be reduced or increased in size to produce any level of total cost or benefit, such comparisons can be made. A cost-effectiveness ratio (CER), defined as costs divided by benefits, can be calculated in order to do this. The CER most often used in health economics is called an incremental CER, or ICER, where the costs and benefits of each alternative are calculated compared with their next best alternative, rather than with a common alternative.

The measurement principle for CEA is that costs are measured in terms of money, but that benefits are measured in units other than money. However, unlike CCA, all of the benefits are measured in the same units, usually because only one type of benefit is considered. The obvious consequence of this is that costs and benefits are not weighed against each other. The ICER simply shows the cost of obtaining a unit of benefit. Whether that cost is worth incurring is a different question. So, unlike CBA, which tells us whether or not health programmes or treatment are an efficient use of resources, CEA tells us which of the possible ways of providing those is the most efficient.

Drummond et al. (2005) restrict the use of the term CEA in two ways. First, they regard CEA as being applicable only when both the costs and benefits differ between alternatives. The case where benefits are the same but costs differ is called cost-minimization analysis (CMA). In practice, this term is rarely used to describe analyses that have been carried out, although such analyses may well be quite widespread. Secondly, they restrict the measurement of benefits to be in what they call ‘natural’ units, such as numbers of cases detected, changes in clinical measures like blood pressure, or changes in undesirable biological markers. This contrasts with the measurement of benefits in terms of changes in health-related quality of life,

which is often given the label cost-utility analysis (CUA), discussed in the following subsection.

The first decision rule for this kind of CEA is that we should reject any alternatives that are dominated by another alternative or combination of alternatives. This is economic efficiency in the strict sense described earlier, where the dominated alternative has a greater cost with no greater benefits or lower benefits with the same or greater costs. The choice between non-dominated alternatives is more complex. Where only one alternative can be chosen, that with the lowest ICER should be chosen, but only if it is below a ceiling ratio, which is a level of the ICER which any alternative must meet if it is to be regarded as cost-effective. Where combinations of more than one alternative can be used, it is in principle necessary to calculate the ICERs for every possible combination to decide which is most efficient and if any meets the ceiling ratio requirement.

These issues are often illustrated using a cost-effectiveness plane diagram (Black 1990) as in Figure 6.6.1. ICERs are presented graphically as a combination of the costs and the effects of a health intervention, described in Figure 6.6.1 as a treatment, compared to some alternative. Costs are conventionally placed on the north-south axis and effects on the east-west axis. In both cases, these effects can be negative, zero, or positive.

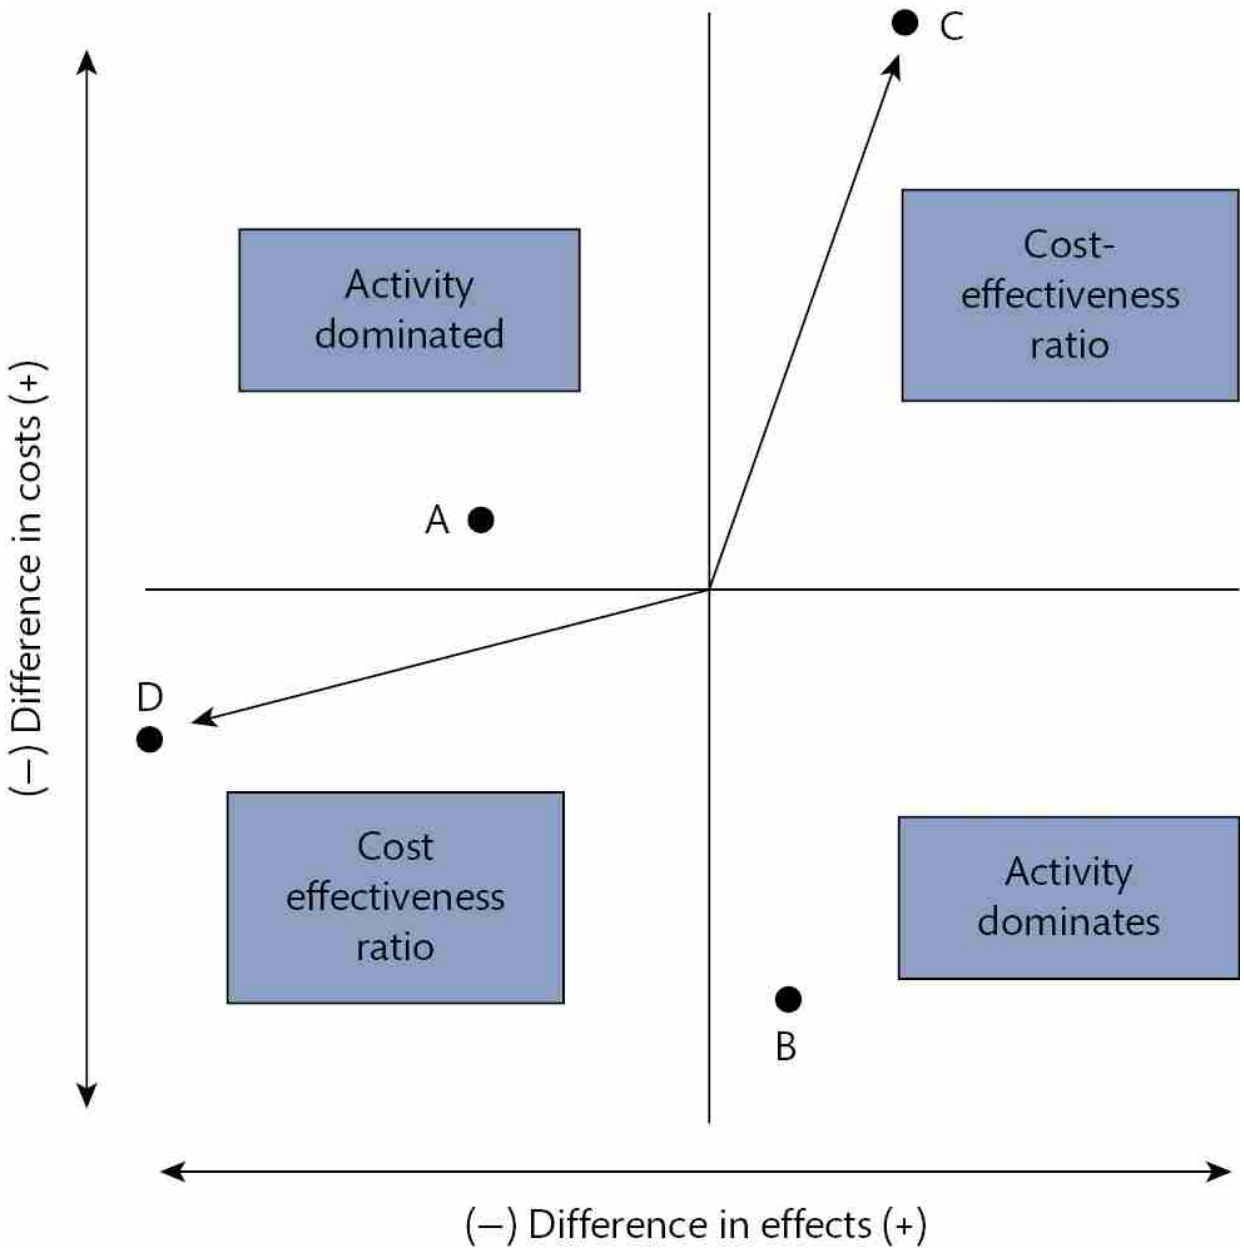

Fig. 6.6.1 The cost-effectiveness plane. An intervention can be placed anywhere on this diagram according to its incremental costs and benefits. If it lies in the northwest quadrant, such as point A, the costs of the intervention are higher than the alternative, and its benefits are lower. It is therefore unambiguously worse and is described as being dominated by the alternative. Similarly, in the southeast quadrant, at a point such as B, costs are lower, and benefits are higher, so the treatment dominates its alternative. In the northeast quadrant, at a point such as C, higher benefits are gained at a net cost over the alternative. So, we can calculate an ICER, the cost per unit of effect gained, measured as the slope of the line from the origin to the point. In the southwest quadrant, at a point such as D, lower costs are possible, but at the expense of lower benefits. Again, we can calculate an ICER, although this now refers to a cost-saving per unit of effect lost, which is again measured as the slope of the line from the origin to the point.

The ceiling ratio can also be demonstrated using a cost-effectiveness plane diagram, where it is often referred to as demonstrating *cost-effectiveness acceptability*, as in Figure 6.6.2.

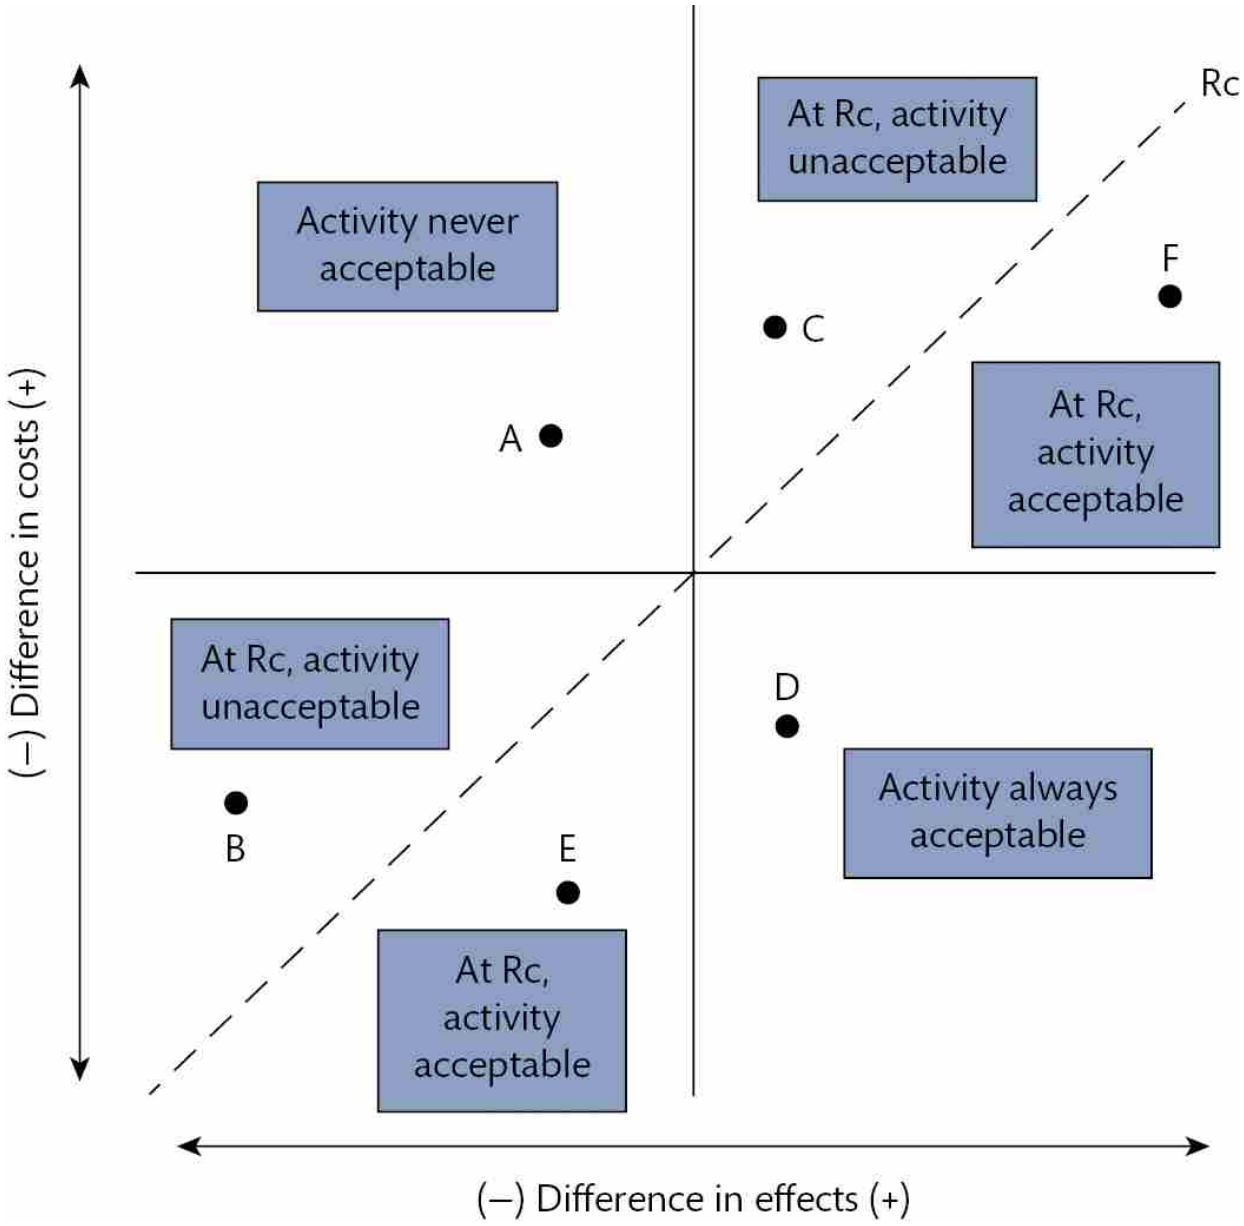

Fig. 6.6.2 Cost-effectiveness acceptability. In this diagram, the dotted diagonal line marked Rc represents the ceiling ratio. If an intervention lies above the line, it will not be acceptable on cost-effectiveness grounds. This is either because it is dominated by the alternative, whatever the ceiling ratio is, as in point A, or its ICER does not satisfy the actual ceiling ratio, as in points B and C. It should be noted that in the south-west quadrant, this means that the ICER is below the ceiling ratio, as in point B, while in the north-east quadrant it is above, as in point C. Below the line it will be acceptable. This is either because it dominates the alternative, as in point D, or its ICER satisfies the ceiling ratio, as in points E and F. In this case, the ICER is above the ceiling ratio in the south-west quadrant, as in point E, or below it in the north-east quadrant, as in point F.

Cost-effectiveness acceptability is also important because it is one way in which uncertainty in EA is dealt with, which is explained later in this

chapter.

Cost-utility analysis

CUA is a term often used in the United Kingdom and elsewhere, though rarely in the United States, to refer to a special form of CEA in which health benefits are measured in terms of quality-adjusted life years (QALYs). QALYs are a composite measure of gains in life expectancy and health-related quality of life, described in more detail next, along with disability-adjusted life years (DALYs). The distinctive outcome of a CUA is the calculation of an ICER in terms of the extra cost per QALY gained (CQG), which may also be thought of as the price of obtaining one extra QALY using a particular healthcare intervention or programme. An example is described in Box 6.6.1.

The rationale for CUA is more complex than that of CEA more generally. QALYs in themselves are regarded by many as a better outcome indicator than the 'natural' units of CEA when appraising therapeutic alternatives for the same condition. This is because they deal with efficiency in the production of health itself rather than simply of healthcare. But CUA also offers something that CEA more generally cannot, which is the possibility of comparing across treatments for different conditions. In principle, it is possible to compare interventions for, say, eating more healthily to reduce weight with, say, reducing alcohol consumption, to determine which is the most efficient at producing health gain in the form of QALYs. Of course, this is controversial. For a CEA restricted to different treatments for a particular condition, it can be assumed that the patients receiving the treatments are the same people, but this will not be true of comparisons across conditions.

Box 6.6.1 A cost-utility analysis of vaccinating schoolgirls against HPV infection

Anonychuk et al. (2009) investigated the cost-effectiveness of vaccinating 12-year-old girls against human papillomavirus (HPV) types 16 and 18 to prevent cervical cancer. The vaccine also cross-protects against other HPV types, and herd immunity effects, the consequent reduction in the risk of infection to non-vaccinated people, determine its overall effectiveness. For each 100,000 girls vaccinated, between 390 and 633 cases of cervical cancer and 168 and 175 deaths would be

prevented, depending on whether or not herd immunity and cross-protection effects are included. This would generate QALY gains of 0.0083 to 0.0095 per person over the group's lifetime. There would be an increase in cost of Can$256 to Can$263 per person. For the base case of no herd immunity or cross-protection effects, Table 6.6.2 shows the costs and effects with and without vaccination.

This gives an extra cost per QALY gained (CQG) of Can$263/0.0083 = Can$31,687. With cross-protection, the CQG was Can$26,947; with herd immunity Can$27,849; and with both Can$18,672. The authors concluded that the vaccine reduced cancer cases and mortality and was cost-effective, though that conclusion does depend on an assumption about the size of the ceiling ratio.

Reproduced under the Creative Commons Attribution License 2.0.

CUA has, in principle, the ability to compare across all health interventions. A contentious implication of this is that it can be used to allocate healthcare resources between different health programmes, and therefore be used to determine healthcare priorities. That would overcome the principal problem that CEA has compared with CBA, because it would indicate whether or not the healthcare benefits from a particular type of healthcare should be realized, rather than simply which is the best way of achieving those benefits. Some people therefore regard CUA as a limited form of CBA rather than a special form of CEA. Viewed in this way, CUA is better than CBA, because it avoids having to measure benefits in terms of money.

To explain this further, recall that a decision rule for CEA is that the ICER of the best alternative is compared to a ceiling ratio. In the case of CUA the ICER is the CQG, so the ceiling ratio is the amount that we think it is reasonable to pay to gain a QALY. This is sometimes referred to as a CQG threshold, because it is the dividing line between healthcare that is regarded as cost-effective and that which is not. NICE has a threshold, which it regards as deriving from the limited budget that the National Health Service has, which determines what can be afforded. This is known as the shadow price of a QALY. Alternatively, it could be set according to what the population is willing to pay for health gain. This is known as the social value of a QALY. But either way, if this is known, it can in principle be used as a means of converting costs to QALYs or vice versa. This puts costs and benefits into the same units, enabling the calculation of net benefits in the same way as for CBA.

Net benefits can be calculated in terms of either money or QALYs. Suppose that an intervention has incremental costs of £30,000 and incremental benefits of 2 QALYs. The ceiling ratio can be regarded as the price that it is acceptable to pay for a QALY, and therefore represents the money value of a QALY. Suppose that the ceiling ratio is £20,000 per QALY gained. If we decide to analyse cost-effectiveness in monetary terms, we first multiply the QALY gain by the ceiling ratio to give the money value of the QALY gain, in this case 2 × £20,000 = £40,000. The net cost is then subtracted from this to give a net monetary benefit of £40,000—£30,000 = £10,000. Alternatively, we could convert the costs to their QALY gain equivalent by dividing the ceiling ratio by them. This would give a net cost equivalent of £30,000/£20,000 = 1.5 QALYs, and an overall net health benefit of 2—1.5 = 0.5 QALYs. Because these are positive—and they must always have the same sign—the intervention is deemed cost-effective.

Of course, this is exactly the same result as if we had calculated the ICER to be £30,000/2 = £15,000 and observed that it is below the ceiling ratio of £20,000. However, this net benefit approach does have an advantage if we do not know the ceiling ratio, since we can calculate net benefits for any value of the ceiling ratio.

Measuring costs

As suggested earlier in the chapter (see ‘Formulating an economic appraisal’), the process of costing involves three steps: identifying and describing resource use changes; quantifying them in physical units; and valuing them.

In general, there are two types of costing: macro- or top-down costing and micro- or bottom-up costing. These are distinguished by the level of disaggregation at which individual resources are measured and valued. In its pure form, macro-costing starts with the total costs incurred by, for example, a hospital, and calculates the costs of, for example a specialty, by allocating a proportion of the total costs to it using some indicator of the costliness of that specialty compared with others. For example, if a specialty had 20% of the hospital’s cases, 20% of the costs would be allocated to it. At the extreme, micro-costing would examine every item of service and every consumable used by every patient. Each item of service would be costed by examining all of the time spent on it by every member of staff as well as the

time spent using every piece of equipment. In practice, these extremes are not found. Moreover, it is common for mixed methods to be used for different elements of cost.

An important consideration is when resources are used, as not all costs are incurred at the same time. This has two important elements. First, if costs occur in different years, then they should be adjusted for any inflation or deflation that has occurred. This is to make the figures comparable over different years and to ensure that it is the value of resources that is considered, which may be unaffected by the rate of inflation. The best practice is to select one year's unit costs and apply them to different years' resource use. But that is rarely possible for many items of cost, so the procedure is to deflate yearly costs by a cost index. This also means that if there are any cost projections, these should not take account of projected inflation.

Secondly, although adjusting for inflation means that each year's costs are measured in the same units of value for each year, this does not mean that every year's costs are of the same value when viewed from a particular year. In particular, people in general prefer to postpone costs if they can, and therefore a cost now has a higher weight than exactly the same money cost incurred in the future. Looked at another way, costs in the future have a lower value now. This is dealt with by discounting, which is a time weight applied to costs, which diminishes the further in the future the cost is. In practice, what is done is to apply a discount rate, which can be viewed as the inverse of an interest rate. Applying an interest rate to an investment means that the value grows over time even if it is fixed. Applying a discount rate means that the value falls over time. In an EA, if costs are summed over time, then discounting all future costs back to the present gives a present value.

The issue of timing may be very important in healthcare, because of the long-lasting effects of many interventions. (Benefits in the future may also have a lower value now, requiring the same approach; this is discussed later in the chapter, see 'Measuring benefit in terms of health gain'). Of particular public health interest is the problem that prevention incurs costs now, and even if it reduces costs in the future by a greater amount, there may not be a net cost-saving if the future costs are discounted. Even if there is a net cost-saving, it will have a lower value than if discounting was not used. In the extreme, measures to deal with maternal nutrition to reduce illness in the

later adult life of their babies, as suggested by the Barker hypothesis (Barker 1992), might see cost reductions so many years in the future that discounting would reduce them to a negligible value.

There is some dispute about exactly what the discount rate to be used should be, and how it should be obtained. There are two competing theories to guide this. One is the social opportunity cost approach, which assumes that public and private investments compete for resources, so the public sector should use market rates of borrowing. The other is the social rate of time preference, which measures what people are willing to receive in compensation for delaying consumption from one year to the next.

Measuring benefits

Measurement of benefits in terms of 'natural' units in a CEA does not require any special economic analysis, and the measurement of diverse benefits within a CCA is too diverse to be dealt with here. This section therefore concentrates on the measurement of health gain for use in a CUA, and the measurement of monetary gain for use in a CBA.

However, a third technique, which does not fit neatly into these two categories, is becoming increasingly important, the Discrete Choice Experiment (DCE). In this, respondents are offered a choice between different interventions, which are described according to attributes that may include health outcomes and price. The choices made reveal the relative values of different attributes. This might be used to ascribe a value to different interventions, or to calculate values in terms of money or to obtain values for different health states. The last of these is described next.

Measuring benefit in terms of health gain

There are many different ways in which health and improvements in health can be measured. Different concepts and measurement techniques are appropriate for different uses. The approaches that are adopted for use in EA are largely determined by the requirements that their use for appraisal purposes dictates.

First, appraisal is attempting to obtain an unambiguous measure of benefit. This implies that the measure of health should be a single number representing all relevant aspects. Secondly, because appraisal looks at the

use of scarce resources that could be devoted to all sorts of healthcare, the measure of health should be capable of comparing those different uses of resources. This implies that a generic measure of health should be used. Thirdly, appraisal compares costs, which represent the value of resources used with benefits, which implies that the measure of health should also be capable of being interpreted as a value.

One measure that meets these requirements is the QALY. This combines length of life and quality of life into a single indicator. Depending on the type of health gain, QALYs can be thought of as a quality adjustment to years of life gained or the length of time for which quality of life is improved or both. It is important to remember that the benefit of a health intervention is the gain in QALYs that it produces. A similar measure is the DALY. This chapter does not describe DALYs fully; such details can be found in Chapter 5.17, which compares the two measures. Essentially, however, the DALY is a population-based measure that combines life expectancy in a population with the prevalence of disability to generate an estimate of a 'health gap'.

Figure 6.6.3 illustrates how in principle QALYs are calculated, for a highly stylized description of prognoses for a disease with and without treatment. For example, suppose that with a particular disease, the prognosis is that a person will live for a further 10 years. During the first two of those, their health-related quality of life (HRQOL) will deteriorate at a constant rate from 80% of full health to 60% and during the last eight will deteriorate more slowly to 30% by the time of their death. This is represented in the diagram by the solid line, with HRQOL values of 0.8 at time t, 0.6 at (t + 2) and 0.3 at (t + 10). With treatment, life expectancy will rise to 12 years, in each of which the patient will enjoy full health. This is shown by the dashed line with HRQOL = 1.0 from time t to (t + 12).

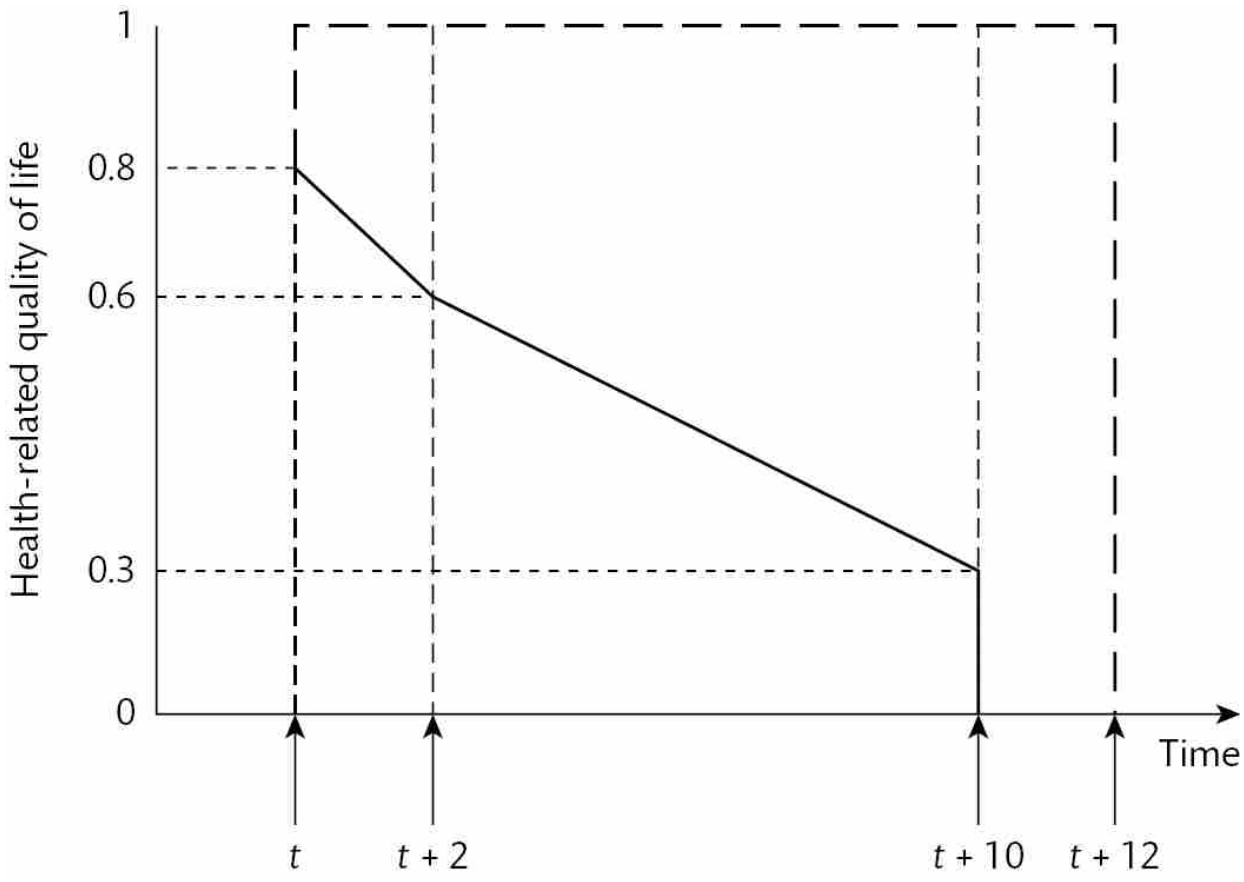

Fig. 6.6.3 Calculating gains in quality-adjusted life years.

The QALY gain can be calculated by subtracting the total QALYs for an untreated patient from the total that they would have if treated. Without the treatment, the patient has 2 years at an average HRQOL of 0.6 = 1.4 QALYs, plus 8 years at an average of 0.45 = 3.6 QALYs, making a total of 5 QALYs. With the treatment, the patient has 12 years at full health, which is 12 QALYs. The gain is therefore 7 QALYs. Equivalently, we can calculate the total gain by summing the gains within each time period. The first 2 years have a HRQOL improvement from an average of 0.7 to 1 = 0.3, giving a QALY gain of 0.6. The next 8 years have an improvement from an average of 0.45 to 1 = 0.55, giving a QALY gain of 4.4. The final 2 years are additional years at full health, which is a gain of 2 QALYs. The total gain is as before 7 QALYs.

One of the big advantages of the QALY is that it can, in principle, be applied to any kind of intervention, whether it raises life expectancy without improving quality of life, improves quality of life without affecting longevity, improves both or improves one at the expense of lowering the

other. However, to some people this is a weakness of QALYs, as they argue that length and quality of life cannot or should not be compared in the same metric.

Before looking at how QALYs are calculated in practice, it should be noted that if QALYs are gained, or indeed lost, at different times, then in principle they should be discounted if they are to be added together, in exactly the same way as costs, if they are to be used in an economic evaluation. There has been a considerable debate about this and there are arguments in favour of discounting both costs and QALYs at the same rate, discounting costs but not QALYs, and discounting them both, but at different rates.

In what follows, the concern is only with the quality of life element of the QALY, since the measurement of life expectancy has no special economic aspects attached to it except for discounting.

In carrying out an appraisal, QALYs can be calculated in a number of different ways. One is to measure the value that patients attach to their quality of life directly. Another is to apply a conversion factor to other indicators of health that will estimate from the indicator a quality of life value. However, an approach which has become most popular, and indeed is recommended by NICE, is to obtain from patients a measure of their health state using a generic health status measure, such as the EQ-5D (Brooks 1996; Herdman et al. 2011), and to apply to the resulting health profile data a value for each state that has been measured for a standard population. The intention is that those values should represent the values of society as a whole.

These sets of values are derived from population surveys. There are different techniques that are used to obtain values, of which the main four are rating or visual analogue scales (VAS), time trade-off (TTO), standard gamble (SG), and the DCE. A VAS usually consists of a single line drawn with verbal and numerical descriptors at each end, describing the meaning of the two ends, such as ‘Best possible health’ and ‘Worst possible health’. Scale markers are often added to the line to denote distance along the line, and these are sometimes also numbered. Respondents are presented with a set of health states and are asked to rate the desirability of each by placing it at some point on the line on or between the two end points.

In the TTO method, respondents are offered a choice between a number of years in full health and a number of years in a particular health state and

asked to choose between them. Slightly different versions of this are used depending on whether the states are chronic or acute state and whether the respondent believes them to be better or worse than being dead. For a chronic health state preferred to death, different numbers of years in full health are offered for a fixed number of years in a health state, until the respondent cannot choose between the alternatives. The value for the health state is then determined by the ratio of the number of years in full health to the number of years in the health state. This calculation is based on the assumed equivalence of the number of QALYs generated by the two alternatives.

In the SG method, respondents are asked to choose between two options. One is that they will be in a specified health state and remain in that state for a given amount of time. The other is that there is a chance that they will either be able to enjoy full health during that time or die before it. Again, slightly different versions of this are used depending on whether the specified health states are chronic or acute and whether the respondent believes them to be better or worse than being dead. For a chronic health state preferred to death, different probabilities of being in full health are offered, until the respondent cannot choose between the alternatives. The value for the health state is equal to the probability at that point of indifference between alternatives. This calculation is based on the expected values of the two alternatives, which is discussed later.

DCEs applied to health state valuation are undertaken by offering respondents a choice between two, or sometimes more, health states and recording their choice. This technique does not measure any individual respondent’s valuations of health states but infers from the responses of a group their collective valuation.

Generic health state measures are usually accompanied by sets of values for each health state that they define. Because they have so many health states, the values are usually generated by a model, which is sometimes called a *multiattribute utility model*, though that label is not explicitly used in some cases and its use in some cases may be disputed. Essentially, health states are decomposed into attributes. Generic health measures usually describe health states using different dimensions, in which people can be at different levels, which form the attributes.

The attributes are combined using a mathematical function to give a single number representing the value for a health state. For example, the widely

used EQ-5D-3L has attached to it a number of value sets that have been calculated and published (Szende et al. 2007). The mathematical form usually used is additive, which means that the attributes are weighted and added together.

Measuring benefit in monetary terms

Monetary measures of benefits can be based on revealed preference or stated preference. Revealed preference techniques use observations from people's behaviour to infer monetary values. As an example, it is possible to examine the value that people place on the avoidance of death or injury by looking at the wages that are paid to people to undertake jobs that differ in the risk of these occurring but are otherwise identical. Stated preference techniques rely on surveys and experiments in which people are essentially asked what monetary value they place on healthcare, or health states, or on other aspects of health benefits. They are not usually asked that question directly, but are given choices between different alternatives, from which money values are inferred.

Such stated preference studies are sometimes called willingness-to-pay studies, although that description is not entirely accurate for all of them. The economic theory underlying these kinds of studies is the measurement of what are called compensating variation and equivalent variation. In the context of measuring the money value of health benefits, these mean monetary payments made by or to a person to compensate for a change in their health, either an improvement or a deterioration, and not having a change in their health, respectively. Willingness to pay refers to compensation paid by the person, either for obtaining an improvement in their health or not having their health deteriorate. Willingness to accept refers to compensation paid to the person, either for having their health deteriorate or not obtaining an improvement in their health.

Although stated preference methods used vary, best practice in economics more generally is to use the contingent valuation method. Contingent valuation requires the survey or experiment to describe a plausible market in which the choices made by respondents about goods reveal the values that are required. The values are said to be contingent on that description. One way to do this is to use a DCE in which price is one of the attributes that the goods have.

Economic appraisal models and uncertainty

In theory, it is possible that an EA could be carried out using one source of data, for example, a clinical trial in which resource use, costs, and quality of life are all measured for individual patients. This would have all of the advantages of a clinical trial in terms of the reliability of results. In practice, EAs are usually based on different sources of data, which have to be linked together. There are many calculations behind the estimates of costs and benefits, which are embodied in what is called an EA model, and in practice all healthcare EAs involve some modelling. In fact, economic modelling is regarded by many as superior to a trial-based EA as it may overcome the problems that trials have in terms of generalisability and speed of producing usable results. Of course, models may use data from trials, but only as one input.

A simple model might be regarded simply as a balance sheet in which the data used to calculate costs and benefits are combined to give figures for total costs and total benefits. However, many EAs cannot use such simple models, and these are no longer regarded as acceptable in the context of technology appraisals examined by bodies such as NICE. The reasons are, first, that treatment options are not always straightforward and clinical decision-making may involve strategies for management, rather than a simple choice between using and not using a single therapy; and secondly, that there is usually some uncertainty about both the model and the data.

As a result, modelling usually uses decision analysis (see, for example, Briggs et al. 2006). This deals both with the complexity issue, by imposing a structure on the implied clinical decision-making, and some aspects of uncertainty. However, there is one aspect of uncertainty that is not dealt with directly by decision analysis, which is uncertainty about the values that data take. A number of techniques have been developed in recent years to deal with this, which are briefly described.

The problem that is dealt with can be encapsulated by the observation that summaries of effectiveness data, such as changes in blood pressure resulting from some intervention, are usually presented as both a point estimate and an interval estimate, or confidence interval, reflecting variability in the data; we should have a similar summary for cost-effectiveness data. When this is done as part of a trial-based analysis it is called stochastic CEA. Unfortunately, there are two problems with this. First, many of the data used

in an EA model are not based on sampling, and therefore do not have a variance that can be used to create an interval estimate. Secondly, the summary index of cost-effectiveness is the ICER, which as a ratio has special problems, such that in general it is not possible to estimate a confidence interval even if all of the data that are used to calculate it do have variability. This second problem applies equally to trial-based and model-based EAs.

Sensitivity analysis

The usual way in which uncertainty is dealt with when using a model is sensitivity analysis. This is a set of techniques that analyse how sensitive the results are to changes in the model, for example, in the data that are contained within it or the way that the data are combined. Some sensitivity analysis techniques are described next. In these, the model that has the best assumed structure and data is called the base case, and the assumptions and data that we wish to test are referred to as the parameters of the model.

One-way sensitivity analysis means looking at how sensitive results are to changes in one parameter. If, for example, a new screening programme is appraised using a model, one of the parameters of the model may be the unit cost of the test used. The base case will use the best estimate that the analyst has of the unit cost as an input to the calculated ICER. One-way sensitivity analysis will calculate the ICER for different values of the unit costs, showing whether the cost makes a lot of or a little difference to the result.

Of course, what is meant by a lot or a little should really be defined. One way to do this is to use the ceiling ratio. If at every possible value of the parameter the ICER remains above or alternatively remains below the ceiling ratio, then the result remains the same, and the decision is not sensitive to the value of the uncertain parameter. In other cases, it may be that at some levels of the parameter for example when the unit cost is low—the ICER will be below the ceiling ratio, but at others—for example, when the unit cost is high the ICER will be above. At some point the ICER will be equal to the ceiling ratio, and at that point called a threshold—a change in the preferred option occurs. This is known as threshold analysis. If the base case and the threshold are very different, then the results are not sensitive to the values of the parameter.

But again, what does very different mean? One way to deal with this is to define upper and lower plausible values for the parameter; for example, with a base case cost of £100 per unit, it may be thought unlikely that the cost could be as high as £200 or as low as £10. This will give a plausible range to the calculated ICER, and if the threshold is within that range, then the results are sensitive to the assumption made.

This can be extended to vary more than one parameter at the same time and to observe the combined impact on the ICER. The ceiling ratio can again be used to define a threshold, and plausible ranges for the ICER can be calculated from the plausible values of the variables, taken in combination. Such multiway analysis is essential, because it is possible that separate one-way analyses of the parameters might suggest that the results are not sensitive to their value, but in combination they might be.

Statistical sensitivity analysis

Plausible range methods are not very satisfactory because their basis is often unclear and not testable. Using statistical methods is better because, as suggested, the base case cost-effectiveness results can be seen as a point estimate and sensitivity analysis as an interval estimate. When this is done as part of a decision analysis model, it is called probabilistic sensitivity analysis.

In this, Monte Carlo simulations are used to generate an ICER distribution. A distribution for each of the model's parameters is assumed, if it is not known. Samples are taken from each distribution, and the ICER is calculated from those simulated data using the model. This is repeated many times to generate an ICER distribution, from which, in principle, a variance might be calculated, and therefore a confidence interval.

Unfortunately, in practice that might still not be possible, because of another problem with ICERs. It is quite possible that the distribution of the ICERs generated by simulation might include both positive and negative values. These mean such different things—a negative value means dominance rather than a true ICER—that a confidence interval calculated from them is meaningless.

There are two possible solutions to this. One is essentially to get rid of the ICER by using the net benefit approach described earlier. Because net benefit is a single number, not a ratio, there is no problem with using

simulation to generate a distribution of it and to calculate a variance and therefore an interval estimate.

Another solution is to generate a cost-effectiveness acceptability curve (CEAC), which retains the CER, but uses a method of describing uncertainty which is different to the confidence interval (van Hout et al. 1994). The simulated ICER values are each compared with a ceiling ratio, and a count is obtained of the proportion of simulated values that are acceptable at that ratio. This is repeated for each possible value of the ceiling ratio, and the proportion that is acceptable will be different for each of those values. A CEAC plots these together, as in Figure 6.6.4. In this illustrative example, the proportion 25% of the simulations of cost and outcomes for a particular therapy are acceptable if the ceiling ratio is £4,500 per QALY gained; 50% if £11,500 and 75% if £20,500. At the ceiling ratio £30,000, 89% are acceptable. Under certain conditions, which are beyond the scope of this chapter to describe, the proportions may be interpreted using a Bayesian approach as probabilities, such that at a ceiling ratio of £30,000, there is a 0.89 probability that the therapy is cost-effective.

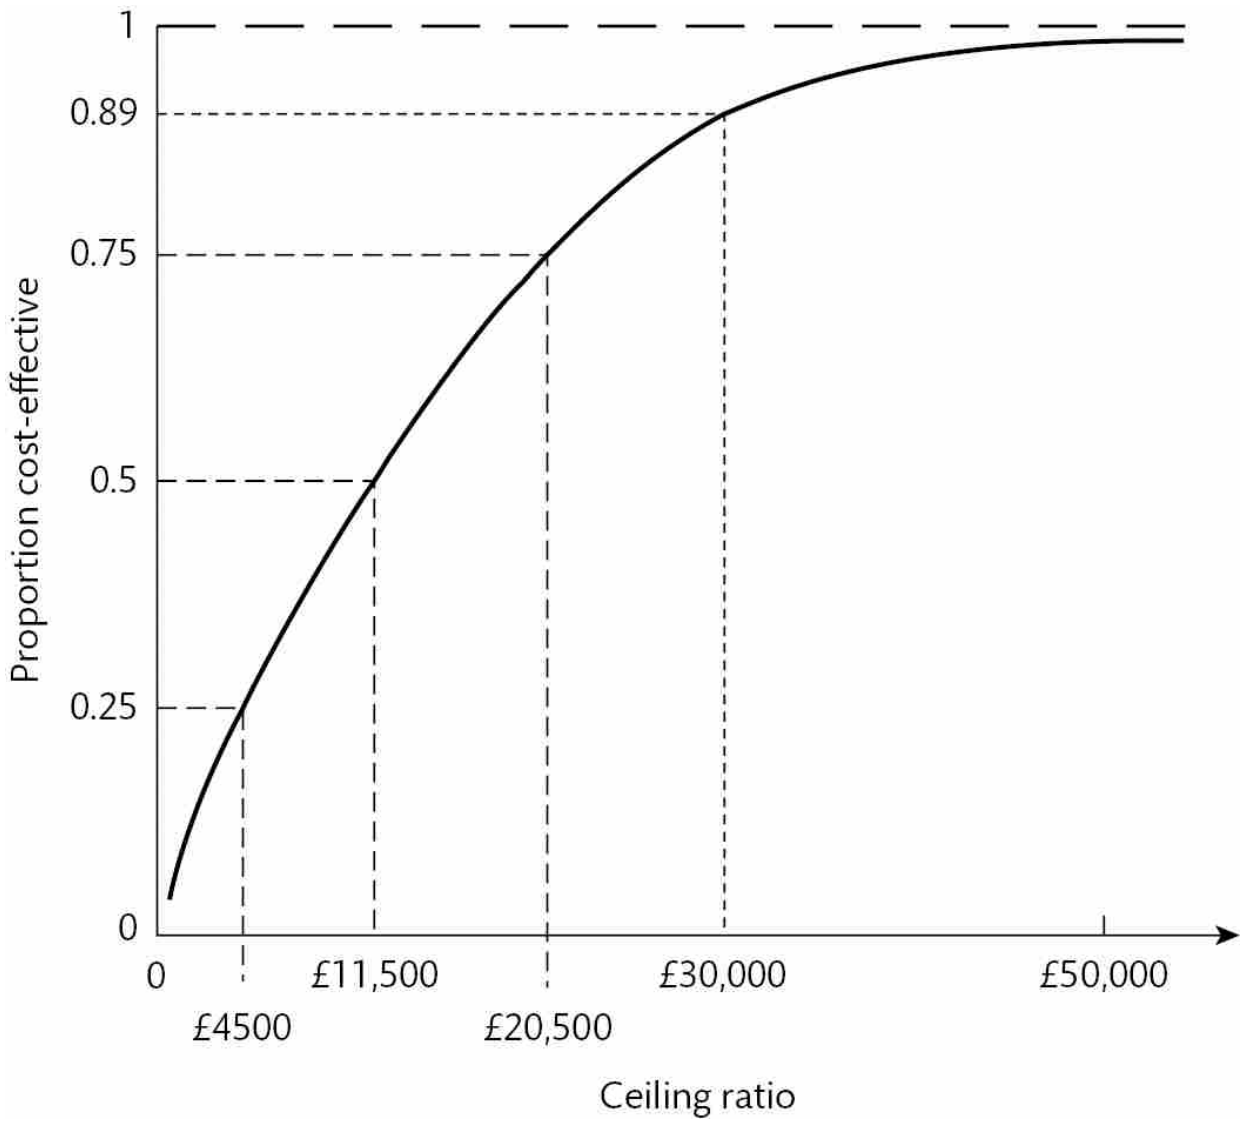

Fig. 6.6.4 Cost-effectiveness acceptability curve.

Decision analysis

Decision analysis is used when the outcomes of decisions are not certain, but the probabilities of different outcomes are known. For example, the treatment of cases detected by a screening programme may not be effective in every case but is known to work in 80% of cases. It is of particular value when decisions involve strategies with different actions. For example, if some members of the population do not respond to a whole population screening initiative, then they may be targeted to increase uptake. Decision

analysis is a way of structuring the different options in order to calculate which of the strategies is best.

Decision analysis relies on the concept of expected values. We can think of the expected value of something as its average value when it is repeated a large number of times. For example, if a treatment produces a gain of 2 QALYs per person in 80% of cases and a gain of 1 QALY per person in the remaining 20%, then out of 100 patients the total gain will be (2 x 80) + (1 x 20) = 180, giving an average of 1.8 QALYs gained per patient. This is the expected value. In reality the nature of uncertainty is such that it is unlikely that the probabilities of 0.8 and 0.2 would produce exactly 80 and 20 in a population of 100, which is why an assumption of large numbers is made. More generally, the expected value is calculated as the sum over all possible outcomes of the probability of the outcome multiplied by the value of the outcome.

Decision analysis calculates the expected values of both costs and benefits and also, though this is a more complicated issue, ICERs. It usually takes the following form, which may be compared with the more general formulation of an EA given earlier:

Structure the problem by constructing a mathematical model of decision-making, usually a decision tree. Identify the decision alternatives; list the possible outcomes of each alternative; and specify the sequence of events.
Assign probabilities to chance events.
Assign values to all possible outcomes of chance events.
Calculate the expected value of each strategy.
Perform sensitivity analyses by systematically changing the assumptions in (1)—(3) to see the impact on the result of (4).

An extension of decision analysis, which is however not yet well established in practical decision-making, is value of information analysis. Decision analysis is based on choosing the alternative that has the highest expected value given current information. The value of information approach analyses the consequences of making the wrong choice, with the aim of assessing how much it is worth spending to improve information so that we do not make the wrong choice. If an incorrect choice is made, the loss incurred is the outcome from the option chosen minus the expected value of the best alternative option. Multiplying this loss by the probability that the incorrect option is chosen gives its expected value. This gives the value of perfect

information; it is worth paying up to this value to avoid making the incorrect choice and therefore investing in research into probabilities of events, quality of life, and costs. Using statistical information on levels of significance and power, it is also possible to estimate the value of sample information, which gives the amount that it is worth paying for a sample of given size to improve information.

Economic appraisal and equity

In discussing equity, we noted that Culyer and Bombard (2012) have suggested using a checklist to ensure that decision-makers take all aspects of equity into account. Here we describe some equity analyses related to EAs and concerning the distribution of healthcare resources and outcomes between people.

The impact of healthcare interventions is ultimately on individual people, and it is always relevant to examine equity at that level. However, in practice inequities are mostly observed between population groups defined by particular characteristics, for example, people who have serious ill-health or are poor, aged, or children. This is particularly important for public health interventions, which are usually conducted at the population level.

Similarly, although it is always relevant to look at the distributional consequences of decisions about every kind of healthcare, it may be of particular importance for public health interventions, since they may be designed specifically to reduce inequalities in population health. It may be that some interventions that target individuals or groups who are disadvantaged would not be regarded as cost-effective relative to many other interventions. It may also be that some public health interventions, such as those designed to enhance health-promoting lifestyles, may be less effective for those who are disadvantaged, thereby increasing health inequalities. In each case an analysis of the implied trade-off between efficiency and equity is essential.

Despite the near-universal acceptance that assessment of equity is as important as efficiency in EA, this has not been matched by practice. In a systematic review, Sassi et al. (2001) were unable to find any satisfactory equity analyses as part of EAs of healthcare in general; Weatherly et al. (2009) found the same for public health interventions.

Cookson et al. (2009) proposed four possible approaches to analysing equity:

Reviewing existing inequalities related to the topic being appraised. This is not in itself evaluative, but it provides background information and therefore some context to decision-making that is based on an efficiency-oriented EA.
Measuring the redistributive impact of a decision about healthcare, that is a quantitative description of who gains and who loses, and the size of gains and losses. Baeten et al. (2010) proposed that for interventions targeted on a particular group, appraisal might assess outcomes in absolute terms for the targeted group but also relative to groups who are not targeted. Sassi et al. (2001) made similar suggestions for assessing the distributional effects for subgroups: the effect of competing interventions; the effect of selectivity; and the effect of prioritizing over other interventions.
If an intervention generates greater equity, but at the expense of a larger health gain overall, measuring its opportunity cost. This cost is not measured in terms of money, but of health, for example, the number of QALYs that would be lost for the population overall by targeting a particular group.
Cost-effectiveness with equity weights applied to the outcomes for different groups. An example which is in practice applied is the 'end-of-life premium' used by NICE in England, which weighs more highly QALYs generated by interventions where survival without the intervention is short, even if the length of the gain from the intervention is itself short. Baeten et al. (2010) also proposed a variant of this in the form of multicriteria decision analysis (MCDA). In MCDA, decision-makers consider many relevant characteristics of an intervention and explicitly incorporate trade-offs within and between them in the form of relative weights. The proposal is that both efficiency and equity consequences are included in characteristics of intervention, thereby taking both into account. Unlike the other three proposed approaches, explicit weighting requires an extra source of data to generate the weights, rather than using data available from an efficiency-based appraisal.

Baeten et al. (2010) illustrated their proposal with an assessment of equity for breast cancer screening. They applied the redistributive impact assessment and both variants of the equity-weighting approach; these gave very similar conclusions in favour of selectivity on both efficiency and equity grounds.

Cookson et al. (2017) distinguish two types of economic analyses that that address equity-related consequences of health and other policy interventions, *equity impact analysis*, and *equity trade-off analysis*. Equity impact analysis quantifies how the costs and effects of alternative policy options are distributed within and between different subgroups of interest to policymakers. Two examples of this are described next, *Extended cost-effectiveness analysis* (ECEA) and *distributional cost-effectiveness analysis* (DCEA). There are other methods, such as benefit-incidence analysis, that do not have a focus on economic appraisal.

Equity trade-off analysis quantifies trade-offs between the two objectives of improving total health and promoting equity. It is used where the outcomes are either a cost-effective intervention that reduces equity or an equity-improving intervention that is not cost-effective, as in boxes 2 and 3 of the health equity trade-off table described earlier. Two examples of this are *Equity Constraint Analysis* and *Equity-Weighting Analysis*. Equity Constraint Analysis assesses how much health is lost by pursuing a fairer option instead of a more cost-effective option. Such an approach treats equity as a constraint on the aim of maximizing overall health. Equity-Weighting Analysis seeks to quantify the trade-off and enable a decision to be taken using a single criterion. It would assess the relative weights that decision-makers put on the criteria of efficiency and equity, quantifying the strength of concern for equity that would lead them to choose whether or not to implement interventions for which a trade-off exists.

Extended cost-effectiveness analysis

ECEA was originally developed by Verguet, Laxminarayan, and Jamison (2015) for low- and middle-income countries as part of the University of Washington's Disease Control Priorities project. It is similar to a CCA, but is specifically aimed at health policy interventions, and includes effects not just on health but also on other societal concerns, in particular the financial consequences of ill-health, referred to as financial risk protection (FPR). The emphasis is on the distribution of these effects over subgroups of a country's population. ECEA is more of a framework for analysis than a set of techniques and its exact content depends on the nature of the policy and the region to which it is applied (Verguet and Jamison 2016).

Health benefits are defined very widely and could include any measures of mortality and morbidity, including life years, QALYs, DALYs, and cases of individual diseases. FPR mainly covers private expenditures and costs by individual members of the population, including out of pocket payments for medical care, other non-medical out of pocket costs such as transport costs to access care, and time and productivity losses, measured by income foregone. Both efficiency and equity are covered, efficiency by considering the net cost of the policy overall and equity by analysing the impact on the distribution of health and financial benefits on subgroups, in particular lower income groups for FPR.

Distributional cost-effectiveness analysis

DCEA was developed by Asaria et al. (2014) as a framework for incorporating equity concerns into CEA. Its aim is to appraise any type of healthcare intervention that has an explicit health inequality reduction objective. As with ordinary CEA, it focuses on health benefits and healthcare costs, rather than including non-health benefits and costs to other sectors of the economy. It therefore appraises effects on the distribution of health and does not consider other dimensions of equity.

Health benefits are disaggregated according to whichever social groupings are thought to be relevant to decision-makers, such as age, sex, social deprivation, and ethnicity. Costs are converted to a health benefit equivalent using a value reflecting the opportunity cost of the resources used in terms of the health benefits that could have been obtained from their use elsewhere in the healthcare system. These are similarly assigned to the different social groups, resulting in the calculation of a net benefit or loss to each group. By comparing the distribution of health before and after the intervention, an index can be calculated of the change in inequality. An equity trade-off analysis can then be undertaken by comparing the resulting equity change index with the total net health benefits.

Asaria et al. (2015) conducted a DCEA on the UK Bowel Cancer Screening programme, comparing different options, of which there were two that dominated in cost-effectiveness terms, screening plus a reminder to all non-respondents and screening plus a reminder targeted on high-risk groups. The results showed that the targeted reminder resulted in a smaller improvement in health but a larger reduction in health inequalities. The

overall judgement would depend on the degree of aversion to inequalities that decision-makers hold, with greater aversion favouring the targeted reminder option. This would in effect mean that the DCEA included an Equity-Weighting Analysis.

Economic appraisal of public health interventions

This chapter has highlighted some issues that arise in applying EA to specifically public health interventions. The state of the art in addressing these is currently less advanced than for other healthcare programmes. But there are many examples that demonstrate both the value of EA in public health and the value of public health interventions themselves.

In reviewing the state of the art in EA of public health interventions, Weatherly et al. (2009) outlined four key methodological challenges, one of which, the specific concern that public health has for equity, we have already discussed. Of the others, one is the kind of evidence that public health interventions are based on. Guidelines for HTA of interventions with individual patients emphasize that the best source of scientific data is the randomized controlled trial (RCT). However, not only are there fewer RCTs for public health interventions, they are inherently more difficult to conduct. We discussed one of the reasons for this in relation to discounting (see ‘Measuring costs’); the impact of public health interventions may be on a longer time scale than an RCT could plausibly encompass. Other problems include that it may be infeasible to establish controls for population-based interventions such as screening and that pathways of causation between intervention and outcome are often less direct than individual treatments, for example, health education programmes. It is therefore necessary to use other ways of establishing evidence, and to rely on extensive use of modelling.

A second concerns the way in which outcomes are specified and measured. Cost-effectiveness analyses use QALYs or other health measures as their outcome measure and it is arguable that is the correct measure where health gain to individual patients is the main aim. However, in public health interventions not only is health gain difficult to measure, because of the difficulties of establishing evidence that we have discussed, but also because the intervention may have additional goals, or important side effects. These include improving public knowledge and awareness, and the benefit of

reassurance, as well as possible unintended adverse consequences such as false reassurance and raised anxiety over possible health problems.

The third concerns the boundaries given to the costs and benefits that are included in an EA. Previously we stated that a social perspective would include all of these (see ‘Social costs and benefits’), whatever they are, and whoever bears them, but it may be essential to restrict their scope depending on the perspective that is taken. For example, as our discussion of the NICE threshold implies (see ‘Cost-utility analysis’), an HTA for interventions that are paid for by a health agency that has a fixed budget is justified in restricting the scope of costs to those incurred by that agency. However, public health interventions typically have much wider effects on the public sector than the health sector, and indeed on the economy as a whole. In turn, those could impact on health; Weatherly et al. (2009) suggest as an example that ‘improvements in housing could reduce illness and injuries, with consequent reductions in healthcare utilization’.

Walker et al. (2019) have outlined a structured way of considering these issues using an ‘impact inventory’. In this the multiple social concerns of interest to decision-makers are specified as different dimensions that might be affected by a policy decision. The inventory contains the impacts of a policy within the different dimensions on different individuals or social groups, both outcomes and costs. This enables aggregate effects to be summed either within dimensions or within individuals or groups. Weighting of dimensions and of individuals or groups would enable a judgement to be made about the policy’s overall net benefit or cost, incorporating any equity concerns.

Despite these problems, there are reasons to be optimistic both about the possibilities of undertaking EA in public health and also about the results from such analyses. Owen et al. (2012) examined the economic analyses that formed the evidence base for public health guidance by NICE issued from 2006 to 2010, an example of which is described in Box 6.6.2; this was extended to the period 2011 to 2016 by Owen et al. (2018). Of 200 cost-effectiveness analyses identified from 2006 to 2010, 30 of the interventions both improved outcomes and lowered costs, in other words dominated the alternative and were in the south-east quadrant of the cost-effectiveness plane. One hundred and forty-one had CERs below NICE’s official stated ‘lower threshold’ of £20,000 per QALY gained, with a median of £1,020; a further seven were below the ‘upper threshold’ of £30,000, with a median of

£25,150; and 11 were above that, with a median of £90,786. Eleven were dominated, that is in the north-west quadrant where costs are higher and benefits lower. For 2011 to 2016, 138 CERs were estimated, with a substantially higher median ICER than for 2006 to 2010 (£7,843 compared with £1,053). There was also greater variability, with both a higher proportion that were cost-saving, but also a higher proportion that were over the £20,000 per QALY threshold. Overall, 63% of public health interventions assessed from 2006 to 2016 were judged to be cost-effective.

Box 6.6.2 Economic analysis of interventions to prevent smoking among schoolchildren

An example is the evidence review underlying NICE guidance on public health interventions to prevent the uptake of smoking among schoolchildren (Jit et al. 2009). A literature review was undertaken and no published economic evaluations of school-based smoking prevention programmes in the United Kingdom were identified. It was argued that studies based in other countries were of limited relevance to the United Kingdom because of differences in the populations being studied and the methodological framework used. In addition, most studies assumed that school-based smoking prevention programmes achieved a lasting reduction in smoking prevalence beyond school age, and this finding was not supported by evidence used to produce the guidance. As a consequence, the authors undertook new research to evaluate whether or not the implementation of a school-based smoking prevention initiative would be cost-effective.

Survey data were used to quantify the association between the age at which smoking was initiated and the probability of quitting smoking quit in later life (older age at initiation was significantly associated with an increased likelihood of quitting in later life). A systematic review was undertaken to quantify the impact of smoking prevention programmes on decreasing smoking uptake in the long term and delaying the onset of smoking, and whether these effects varied by the age of the participants.

These data were combined with cost and other data in an economic model and used to calculate the cost-effectiveness of school-based smoking prevention programmes. Results were presented for a generic programme delivered to 11-year-old students. Assuming an intervention cost of £38.50 per participant the CQG was estimated to be £2,030–12,700, depending on assumptions made about the persistence of effect of the programme over time. The results were fairly robust to changes in key model parameters concerning the association between age of smoking initiation and probability of smoking in later life, mortality in smokers and non-smokers, health-related quality of life in smokers, lifetime medical costs of smokers, and the quality of the studies used to inform the models. In few cases was the extra CQG greater than the ceiling ratio, which was assumed to be £20,000 per QALY gained.

Of course, these samples are only from England, and the coverage may not be representative of the broad range of public health interventions; 127 of the original 200 were related to smoking and other interventions may not

have been selected for evaluation if they were considered unlikely to be cost-effective. Nevertheless, they did cover very different types of interventions to very different sections of the population. An important finding was that interventions aimed at the population as a whole produced the lowest costs per QALY gained.

Masters et al. (2017) conducted a systematic review of published economic appraisals of public health interventions, restricted to high-income countries with universal healthcare, including the Western Europe, the United States, Canada, Japan, Australia, and New Zealand. Their focus was on papers that enabled the calculation of a *benefit-cost ratio*, called by the authors a cost-benefit ratio (CBR), or a *return on investment (ROI)*, which are alternatives to net benefit as a way of summarizing a CBA. The ROI is a concept derived from financial appraisal, measuring the gains derived from an investment as a ratio of gains to cost. In this context it is the ratio of net benefits to cost, equal to the benefit-cost ratio minus 1.

They identified 52 studies from which a ROI could be calculated. For public health interventions as a whole, the median ROI was 14.3, and median CBR was 8.3. As with the NICE study, interventions at the national level produced a greater return (ROI 27.2, CBR 17.5) than those at the local level (ROI 4.1, CBR 10.3). One of the issues with financing public health interventions is that there is often a long time from incurring costs to realizing benefits, in many cases 10–20 years. However, the returns identified were in some cases realized within a short period, for example falls prevention interventions had a ROI of 20.6, much of which was achieved within 6–12 months.

Efficiency and equity in the economics sense are not the only considerations for decisions in public health or healthcare in general, and EA is only one of the types of evidence that are relevant to them. However, EA is a powerful way of assessing evidence about important consequences of such decisions, and in particular helps in considering how to manage scarce healthcare resources. In advocating that public health should receive a fair share of those resources, it is essential to base arguments that are as strong as those for other types of healthcare and to use equally powerful techniques for analysing them.

Table 6.6.2 Incremental costs and QALY gains from vaccination

	Non-vaccinated	Vaccinated	Difference
Total cost (Can$)	476	739	263
Total QALYs	30.5015	30.5098	0.0083

Behavioural economics and health

Alison Buttenheim and Harsha Thirumurthy

Introduction

Among the many determinants of health outcomes around the world, human behaviour plays a central role. While resources allocated to the health sector and access to health products or services are certainly important, it is often the case that individual decision-making influences the burden of disease and the effectiveness of health services available in any given country. Examples of why human behaviour is relevant are numerous in both low- and high-income settings. Behaviours such as smoking and exercise have an impact on the burden of non-communicable diseases (NCDs) globally. Utilization of vaccination services and infant feeding behaviours have an impact on child health outcomes. Understanding human behaviour—specifically how people make health-related decisions—is therefore essential for explaining health outcomes around the world and also for developing solutions to leading challenges in global health. This understanding can be advanced and enriched using behavioural economics.

Behavioural economics blends theories from the disciplines of economics and psychology to uncover key insights about human decision-making. In recent years, a rapidly expanding literature has applied behavioural economics specifically in the health domain. Behavioural economics insights have been useful for understanding why proven health interventions are not taken up at the ‘last mile’, or why it is difficult to sustain healthy behaviours like smoking cessation or medication adherence. Relevant for health policy, the field of behavioural economics has also brought to light a number of interventions that can contribute meaningfully to efforts to improve population health.

This chapter introduces several prominent theories from behavioural economics and reviews examples of how these theories can be useful for studying global health and developing policies or programmes to improve health. We begin by reviewing the 'standard' theory or model of decision-making that features prominently in economics. This model posits a form of rational decision-making and offers valuable insights about what drives individuals' decisions in various domains of life, from consumption to health. We discuss several policy implications that follow from this theory and make a case for why these are important for global health policy. We then turn to theories and principles from behavioural economics and adjacent fields that emerged from a recognition that the standard economic model of decision-making does not adequately explain many aspects of human behaviour. We discuss these anomalies—departures from rational decision-making models—and summarize behavioural economics theories that better explain human behaviour. In parallel, we draw upon empirical evidence from around the world and highlight actionable behaviour change interventions that can be useful for students of global health and practitioners alike.

Given the breadth of behavioural economics theories and empirical evidence, we are necessarily selective in our review of this discipline and its relevance for global health. We focus on a few prominent theories of decision-making that are key to understanding and modifying human behaviour. We introduce the concept of present bias, which is particularly relevant for understanding health behaviours in which the consequences of one's actions are not realized immediately. Present bias in individuals' decision-making offers a compelling rationale for offering incentives—a widely-studied topic for which we summarize key studies and lessons. We also review the concepts of loss aversion, status quo bias, limited attention, and social influence, all of which have direct relevance for health behaviour and health policy. Our chapter concludes by reviewing more recent theories of the link between poverty and decision-making that offer new ways of understanding health behaviour and new opportunities for interventions that improve health.

Empirical examples in this chapter come from diverse settings, including both low- and middle-income countries (LMICs) and high-income countries, and from diverse areas of health, from infectious diseases such as

HIV and malaria for which the burden is greatest in low-income regions of the world to NCDs that are common globally.

Standard economic theories of decision-making

To explain human behaviour and develop behaviour change interventions, the field of economics has commonly relied on a model grounded in the assumption that individuals are rational, self-interested decision makers who seek to maximize their own well-being. This workhorse model in economics offers a number of relevant insights for global health. The model posits three factors that drive choices: preferences that characterize tastes and values, the relative prices faced for the various choices available, and the constraints on available resources such as time or money. Preferences describe individuals' likes and dislikes as well as the extent to which they value the present relative to the future and the degree of risk or uncertainty they are willing to tolerate—all of which can influence one's propensity to make specific choices. Prices reflect the costs of purchasing products and services. And finally, resource constraints are typically denominated in income or wealth, but can also appear as time constraints. We discuss each of these in more detail next.

Preferences are an important determinant of human behaviour that vary from person to person. For a number of health behaviours, it is easy to see why preferences might be relevant. Some individuals may place a greater value than others do on future costs or benefits of actions they take today, and as a result may be less likely to smoke cigarettes or more likely to adhere to medications. These temporal preferences have been shown to be associated with both health behaviours and outcomes in several studies (Thirumurthy et al. 2015; Bradford et al. 2017). Preferences towards risk are another relevant decision-making factor. Heterogeneity in risk preferences and the association between risk preferences and risky health behaviours have been documented in many studies (Anderson and Mellor 2008). Behavioural economics research discussed next raises doubts about the within-person stability of time and risk preferences, but standard economic theory treats risk and time preferences as not easily malleable.

Beyond time and risk preferences, individuals' propensity to use various health services or to engage in healthy behaviours can also be influenced by

the information they possess about associated benefits (or harms). This has motivated a large literature testing whether information provision to individuals can influence decision-making, and a common approach to public health campaigns of raising awareness about the benefits of healthy behaviours or the harms of unhealthy behaviours. Empirical evidence on the effects of information provision is mixed. Some studies have documented large impacts of one-time information provision. In Kenya, informing teenage girls about the risk of unsafe sex with older men who have a higher likelihood of being HIV-positive led to sexual behaviour change and reduced pregnancy risk for the girls (Dupas 2011). Larger-scale testing of this approach in other countries has shown more muted effects, however. In the United States, researchers and policymakers have sought to influence food choices by providing caloric and other nutrition information on food items. Again, there is some evidence that this type of information provision can alter people's preferences and ultimately, their behaviour (Wisdom et al. 2010). These examples underscore the importance of paying attention to individuals' preferences when designing public health interventions.

The second determinant of health behaviour—prices—is highly relevant for understanding health behaviour and continues to shape health policy in important ways. A large literature has shown that prices of health products and services influence demand. Price experiments in high- and low-income countries have shown that demand for healthcare—in much the same way as demand for consumer products—is highly sensitive to prices. The RAND health insurance experiment showed long ago that healthcare utilization is driven by the prices people face (Manning et al. 1987). In low-income countries, a series of randomized trials has demonstrated that people's demand for life-saving health products and services is highly sensitive to prices even when prices are extremely low. One study from Zambia showed that demand for water treatment products declined substantially when going from free distribution to prices just above zero (Dupas 2014). Similarly, a recent study in Zimbabwe showed there was a 25% decline is demand for HIV self-tests among people offered self-tests for $0.50 instead of being offered them for free (Chang et al. 2019). A key lesson that emerges from these studies in low-income countries is that there is a compelling rationale for subsidizing healthcare products and services instead of charging user fees for them. This is especially the case for health products and services

associated with infectious diseases, where usage by one individual can influence health outcomes of other individuals.

In addition to public subsidies, two other policy measures also follow directly from the recognition that prices influence people's decisions. One is the use of taxes to raise the prices faced by individuals and thereby curb certain unhealthy behaviours. Another is the provision of financial incentives to increase benefits associated with a certain health behaviour and thereby promote health behaviours. Taxes are a widely-used policy measure not only for raising government revenue but also for changing human behaviour. Cigarette taxes are perhaps the most prominent example of taxes as a lever for behaviour change in global health. Multiple studies have shown that taxes are an effective way to reduce smoking rates. More recently, in response to growing concern about rising obesity, some governments have begun to impose taxes on sugar-sweetened beverages. Studies from Mexico as well as individual cities in the United States have suggested that this is one way to reduce sugar-sweetened beverage consumption (Colchero et al. 2016; Silver et al. 2017; Roberto et al. 2019). Financial incentives (which we discuss in the next section in the context of present bias) have a clear and compelling rationale even in the standard model of decision-making. Just as subsidies lower the prices faced by consumers and thereby boost demand, incentives can offset various opportunity costs associated with seeking health services and bring down the full price faced by consumers.

Resources available to individuals are the third and final determinant of health behaviour in standard models of decision-making. A core prediction of economic theory is that all else equal, individuals facing financial or time constraints will be less able to access healthcare than those without such constraints. This provides further motivation for interventions such as price subsidies or health insurance; in recent years there have been a number of efforts in LMICs to expand access to health insurance. Another policy response to curb the effects of poverty on health has been the provision of unconditional cash transfers. Many countries in Africa and Asia have expanded unconditional cash transfer programmes with the goal of both alleviating poverty and improving health outcomes. Later in this chapter we discuss additional ways in which poverty can influence health outcomes by summarizing recent research on the psychological consequences of poverty.

Behavioural economics insights and related interventions

Behavioural economics theories have gained prominence in the study of health behaviour because the standard economic models of decision-making outlined earlier, while useful for explaining many facets of decision-making, fail to explain some commonly-observed patterns of behaviour. For example, even when life-saving health technologies and services are available for free or at very low prices, individuals do not utilize them at the high rates that would be predicted by standard economic theory and keenly desired by health officials. Similarly, despite medications for chronic diseases having large benefits that people recognize as important and valuable, medication adherence remains far lower than desired. These and many other behavioural 'anomalies' have underscored the limitations of standard models of decision-making and given rise to the behavioural economics theories that we discuss next.

Present bias and the rationale for incentives

Perhaps the most prominent and widely discussed decision-making context is situations that involve trade-offs between present and future costs and benefits. Seeking preventive services or exercising regularly, for example, requires incurring immediate economic costs, time investment, or other disutility in order to realize health benefits in the future. For such decisions, pervasive in the health domain, individuals do not discount future costs and benefits according to a consistent discount rate, but rather do so in ways that are *present-biased*. Specifically, the immediacy of costs and benefits drives behaviour to a much greater extent that would be expected from the rational tendency to discount the future. Thus, even with large benefits to adopting certain health behaviours such as quitting smoking, exercising, taking medications, or seeking preventive services, individuals may fail to adopt if the benefits are delayed and the costs (in the form of economic costs, inconvenience, or psychological burdens) are immediate. Present-biased preferences have been documented in lab and field settings and go a long way towards explaining why behaviour change can be difficult when there are intertemporal trade-offs.

An important implication of present-biased decision-making is that people can be guided towards engaging in more forward-looking, healthy

behaviours if the immediate benefits of engaging in the behaviour are enhanced or the immediate costs are lowered. This insight motivates the widespread use of financial and non-financial incentives for healthy behaviours in many parts of the world. Since the future benefits of engaging in a healthy behaviour are often insufficient for promoting the behaviour, the provision of small, immediate rewards can accelerate benefits into the present and make the behaviour more likely. They can also offset the disproportionate role of immediate costs or hassle factors. A vast empirical literature has examined the effects of incentive-based interventions on behaviour change around the world. The provision of incentives by employers and governments is also widespread. A few examples illustrate the ways in which incentives and highlight the strengths and limitations of such interventions to promote better health. An early and prominent example of deploying incentives to motivate health behaviours in LMICs is the *Progresa* programme implemented in Mexico beginning in the 1990s and later renamed the *Oportunidades* programme. In this programme, low-income households could receive cash transfers from the government contingent on children in those households attending school regularly and obtaining preventive healthcare. While present-biased decision-making was not the sole rationale for the conditional cash transfers—the programme crucially also sought to alleviate poverty—the interventions succeeded in part by offering more immediate rewards to households for engaging in behaviours that would generate long-term benefits. Various studies have evaluated the Progresa programme and demonstrated that it was largely successful in promoting behaviour change (Paul Schultz 2004; Fernald et al. 2009).

A growing number of randomized trials have also examined the effects of very small incentives in promoting individual health behaviours such as HIV testing, medical male circumcision for HIV prevention, and vaccination uptake. In many of these cases, even though the health services were provided at no cost to individuals, utilization was well below desired levels and incentives succeeded in increasing utilization rates. One study conducted in rural India examined the effects of bringing reliable, monthly immunization services closer to communities and providing caregivers non-financial incentives worth approximately $1 per immunization administered (Banerjee et al. 2010). Rates of full immunization were significantly higher in the villages randomized to receive reliable services and incentives (39%)

as compared to villages that only received reliable services (18%) and to control villages (6%). Another randomized trial conducted in rural Malawi showed that small financial incentives ranging from $0.20 to $3 led to significant increase in HIV testing uptake among adults (Thornton 2008). Individuals who received some incentive were more than twice as likely to obtain their HIV test results as those who did not. Finally, several studies have also tested whether the provision of relatively small non-financial incentives increases uptake of medical male circumcision in settings with a high prevalence of HIV. Even though medical male circumcision reduces men's risk of HIV acquisition by 60%, uptake has been low in settings where free circumcision services have been made available. Present-biased decision-making is one of several reasons why uptake may be low, as several costs of getting circumcised are relatively immediate (taking time off from work, fear of pain, and sexual abstinence for up to 6 weeks) whereas the benefits are distributed over a future time horizon. Studies in Kenya and Zambia have shown that small incentives worth as little as $9 can significantly increase uptake among adult men. One randomized trial found that uptake in a 2-month period was below 2% among men offered no incentives but considerably higher among those offered incentives of $9 and $15 (6.6% and 9.0%) (Thirumurthy et al. 2014). The use of incentives to promote specific health behaviours is by no means widespread in LMICs, but there are high-profile examples of such incentive programmes being implemented at scale. In India, for example, the government has introduced several schemes that provide pregnant women cash transfers contingent on their use of prenatal health services and contingent on facility-based deliveries.

Incentives to promote health behaviours have not always succeeded, however, and there are a number of lessons to be learned from these examples as well. Incentives have generally been less effective in promoting sustained behaviour change. For example, medication adherence, which often requires frequent, nearly daily pill-taking is more difficult to promote with incentives that less-frequent, one-time health behaviours. A recent study in Uganda, for example, found that financial incentives did not increase viral suppression rates among HIV-positive adults taking antiretroviral therapy (ART) (Thirumurthy et al. 2019) while some other studies have shown that incentives do have promise as an adherence intervention (Linnemayr et al. 2017; McCoy et al. 2017). In practice, for

incentive interventions to succeed it is important that incentive payments be delivered as close in time to the behaviours that is of interest. For example, an incentive to promote daily pill-taking is less likely to be effective if payments are not made on a nearly daily basis and instead made at the end of the month. With rising ownership of mobile phones and new technologies that make it possible to monitor behaviours like medication adherence or daily exercise (such as physical activity monitors), the potential for devising more effective incentive-based interventions is likely to grow. Costs and feasibility of implementing these interventions at scale in low-income settings remain a limitation, however. Further below, we draw attention to interventions that rely on social incentives to promote behaviour change rather than financial incentives.

Loss aversion and the endowment effect

Another finding in the behavioural economics literature that goes against traditional economic theory is the endowment effect, which predicts that we value something we own (or have been 'endowed' with) more than we value the same item if we are asked to pay for it. The general principle underlying the endowment effect is loss aversion, or our tendency to weight losses more heavily than a comparable gain (Kahneman et al. 1991). We are made more unhappy by the loss of $20 than we are made happy by the gain of $20. This asymmetry also stands in stark contrast to traditional economic theory, which predicts that we should value that $20 equivalently whether it's headed into our wallet or out of it.

Loss aversion can be leveraged in the design of financial incentives to promote behaviour change. Instead of earning incentives prospectively (for example, receiving a weekly payment for a negative cotinine test as evidence of smoking cessation, or for meeting physical activity targets), participants can receive incentives up front (an endowment of sorts) but lose some of the incentive if they fail to meet targets. To leverage loss aversion even further, deposit contract or commitment contract schemes ask participants to put up their own funds, which they risk losing if behaviour goals are not met. In high-income settings, these types of incentives that leverage loss aversion have been shown repeatedly to be more effective than standard, gain-framed (prospectively-earned) incentives (Halpern et al. 2015). In the Philippines, the CARES programme offered smokers the

opportunity to deposit funds into a savings account. If a urine test at six months showed abstinence from smoking, the savings were returned; if not, the accumulated funds were donated to charity. Among smokers who took the offer and were followed up at 6 months, 35% were biochemically confirmed to have quit smoking. While only 11% of those offered the programme took it up, quit rates among those offered the programme were 3 percentage points higher than those not offered the programme (Giné et al. 2010). The selection into such commitment contracts is of course an important aspect of these programmes, and may reveal higher levels of readiness to quit, self-awareness, or optimism about having a successful quit attempt.

Loss aversion can also inform the design of public health information campaigns and other information-provision interventions. People respond differently to the same information when framed as a loss compared to a gain frame. In general, people tend to exhibit more risk aversion in response to gain frames and are more risk-seeking or more tolerant of risk in response to loss frames (Kahneman and Tversky 1979; Rothman et al. 1999). In a multi-country test of household use of water treatment technologies, messages that included both loss and gain messages were more motivating than gain-framed only messages (Luoto et al. 2014). Loss aversion may also shape how consumers respond to prices. For example, discounts on health-promoting items may feel like a gain and may therefore be less persuasive than taxes on unhealthy items, which may feel like a loss (Cawley 2011). Similarly, choices about purchasing or joining health insurance schemes may be shaped by the relative cost burden of premiums (a price, which may not invoke loss aversion) vs. deductibles, which must be paid following care and may feel like a loss (Rice 2013).

Just as loss aversion can be leveraged to strengthen the effectiveness of financial incentives, other insights from behavioural economics are also relevant when designing incentive interventions. The tendency for individuals to overestimate the likelihood of low-probability events (known as base rate neglect) has been used to motivate lottery-based rewards for engaging in healthy behaviours. Several studies have tested whether lottery-based incentives are effective. One randomized trial in Lesotho found that providing lottery-based rewards to individuals if they did not obtain sexually transmitted infections (STIs) led to a large and significant reduction in HIV incidence (Björkman Nyqvist et al. 2018). Another study

conducted in rural Uganda found that lottery-based incentives worth about $1 per person were more effective in increasing HIV testing uptake than standard, gain-framed incentives worth the same amount (Chamie et al. 2018). The implication therefore is that incentives may be more effective if they are offered in the form of lotteries—with some individuals receiving a large reward and others receiving a small reward or no reward. That said, the context in which incentives are provided and the specific behaviours being targeted are also relevant, as several studies have shown that lottery-based rewards are not more effective than no incentives or standard incentives (Thirumurthy et al. 2016; Buttenheim et al. 2018).

Status quo bias and defaults

Humans have a strong tendency to stick with the status quo. We prefer the option placed in front of us—the default—over having to invest cognitive and decision-making effort to choose a different option. This so-called status quo bias explains many behaviours, from continuing magazine subscriptions that automatically renew each year to accepting the side dishes that automatically come with a fast-food meal. Status quo bias is another adaptive heuristic that can lead to suboptimal health behaviours and decisions. Status quo bias is adaptive in that it conserves limited attention span and bandwidth: if we had to thoroughly evaluate all available options for every choice we are presented with in the course of decision-rich day, we would quickly fatigue. Status quo bias can be maladaptive, however, when it causes us to remain with a preselected option purely because it is the default.

The pervasiveness of status quo bias makes the design of default options very important in health interventions of all kinds. Of all the popular nudge approaches, defaults have consistently been shown to be the most effective and powerful. While status quo bias is likely the most powerful engine of defaults (it is simply easier to stay with the default option, and inertia will likely keep us from investing time and effort to switch), defaults are powerful nudges for other reasons as well: default options may also carry some implicit level of endorsement from the choice architect—if this is default option, someone must have thought it was a good idea. Two other behavioural economic concepts may also contribute to the power of defaults: because switching to another option from the one you already have

may be perceived as a potential original option, loss aversion may come into play. Additionally, omission bias predicts that we prefer doing nothing to doing something, particularly when there may be negative consequences to our (in)action. Omission bias will make the default option seem even more attractive compared to taking action to switch to a different choice (Johnson and Goldstein 2003).

There are many compelling empirical examples of successful defaults to change health behaviour in both high-income and LMIC settings. All opt-out screening or testing programmes employ defaults, as the patient will be automatically screened or tested unless they proactively decline. Opt-out testing for HIV has been widely scaledup across several countries in sub-Saharan Africa in diverse care settings and for different populations. In general, opt-out testing is highly effective in boosting testing rates (Steen et al. 2007) and is also feasible and acceptable (April et al. 2009). Some studies suggest that opt-out HIV testing can reduce HIV-related stigma or may be most effective in increasing testing among those with higher perceived stigma (Kaufman et al. 2017). Test-and-treat policies, in which those diagnosed with HIV immediately begin treatment with ART regardless of viral load, CD4 count, or length of time living with infection, also harness the power of defaults. When immediate initiation of treatment is framed as the default, newly diagnosed individuals do not have to make complex decisions about returning for follow-up care, repeated viral load testing, or the optimal time to begin treatment (Linnemayr and Stecher 2015).

Limited attention: availability heuristic and salience bias

Traditional economic theories of decision-making described earlier assume that individuals have complete information about choices and can attend to and process information without constraint. In reality we live in a very information-rich environment, with many demands on our attentional and cognitive resources. To deal with this information overload, we have adaptive strategies to filter out much of the information directed at us and selectively pay attention to signals. These strategies produce predictable biases and heuristic thinking that may lead to less healthy decisions, but that can also be leveraged in health-promoting interventions.

The *availability heuristic* prompts us to estimate the likelihood of an event based on how easily we can think of a recent example of that event (Tversky and Kahneman 1973). Immediately following an infectious disease outbreak, for example, people may overestimate the likelihood of future outbreak or of their own susceptibility to the disease. On the flip side, a community may underestimate the prevalence of a common but 'silent' or stigmatized condition such as mental illness or HIV if individuals cannot easily recall a specific instance of the illness in their network. These biased estimates of risk can then affect decisions about prevention behaviours, including screening or vaccination. A related phenomenon is salience bias, which predicts that we will focus our attention on information that is most unusual, striking, or vivid—that is, more salient. Information (visual or otherwise) that stands in contrast to the surrounding environment is particularly salient—think, for example, of a single red word on a page or a cell phone ringing in a quiet library.

Public health interventions that rely on the provision of information to change behaviour will be most effective if they take the availability heuristic and salience bias into account. This has been shown in particularly compelling way in multiple water, sanitation, and hygiene (WASH) interventions (Cole 2008; Kremer et al. 2009; Luoto et al. 2014). A study in rural India made the safety of household drinking water more salient for households in rural India by conducting a visible chemical test of water contamination in the household's water storage containers and showing households the results (Hamoudi et al. 2012). Dangerous levels of bacterial contamination cannot necessarily be detected by sight or smell, but a chemical test strip showing presence of faecal bacteria makes this information highly salient. Households receiving this intervention were more likely to spend additional financial resources on clean water than controls, although, importantly, they did not invest more time in home-based water handling or treatment measures.

Salience bias can also inform the design and delivery of interventions that use SMS reminders to promote attendance at appointments or adherence to medications. Messages that grab attention with relevant, personalized information that are delivered at the optimal time to promote action have been shown to be highly effective. One study conducted in Kenya, for example, examined the effects of daily and weekly text messages sent to HIV-positive adults taking ART (Pop-Eleches et al. 2011).

Since adherence is important for realizing the health benefits of ART and achieving viral suppression, messages in the study were intended to remind patients to take their medications and also increase their motivation to stay adherent. Over a 12-month period, the study found that patients who received weekly text message reminders were significantly more likely to have medication adherence exceeding 90%. Another study, also conducted in Kenya, found that two-way text messages sent to ART patients on a weekly basis led to significantly higher self-reported adherence as well as higher viral suppression rates (Lester et al. 2010). These promising examples of mHealth interventions have given rise to many other interventions. While such interventions are not uniformly successful, they represent a low-cost, easily testable way to promote behaviour change.

Social norms and social influence

We are very social creatures who look to the actions of others to guide our own decisions and behaviours. This is another adaptive heuristic mode of thinking that kicks in particularly when information is limited, choices are many, and cognitive bandwidth and attentional resources are constrained. This tendency means that social norms—standards for behaviour shared within a social group—can strongly influence behaviour, far beyond what standard economic theories of decision-making might predict. Social norms theory helpfully distinguishes between descriptive norms (what we see other people do), and injunctive norms (what others believe we ought to do) (Reid et al. 2010). For example, if you decide to take your child to be vaccinated because you observe everyone else in your community doing the same, you are acting on a descriptive norm. If you are told by others in your network that everybody ought to vaccinate their children, and you fear there will be social consequences if you don’t, you are acting on injunctive norms.

The potential for social norms to influence behaviour is evident in an extensive literature describing correlations between descriptive norms and behaviour. An observational study of household participation in a Chagas disease vector control campaign in Peru found that participation decisions were associated with whether neighbours also participated, controlling for other predictors of participation that might also be correlated with neighbour participation (e.g. socioeconomic status, infestation status)

(Buttenheim et al. 2014). Importantly, perceived norms (even if incorrect) can also predict behaviour. Men in a South African township overestimated the prevalence of risky sexual behaviour and underestimated prevalence of condom use among their peers. These behavioural norms correlated with the respondents' own risky behaviours (Carey et al. 2011). Similarly, a study in Uganda found that village residents vastly underestimated the prevalence of HIV testing among other village members (HIV testing was actually a normative behaviour); underestimation was also associated with never having tested (Perkins et al. 2018). Multiple studies have also found a link between social norms (both descriptive and injunctive) and child marriage (Cislaghi et al. 2019).

Of course, these relationships may reflect mere correlation or even reverse causation. Experimental trials of interventions that leverage social norms to change behaviour have had mixed results in LMICs. Two interventions informed by the descriptive work on 'contagious' participation in the vector control campaign in Peru that leveraged social norms in multiple ways were not able to boost household participation beyond the existing campaign (Buttenheim et al. 2018). In a randomized trial of promotion of water treatment products in Bangladesh, willingness to pay for products was not increased by observing neighbour purchases of similar products (Luoto et al. 2012). It should be noted that many of the same successful interventions mentioned earlier to improve hygiene and sanitation behaviours and reduce child marriage have also incorporated social norms as part of complex, multicomponent interventions, making the direct of effect of changing perceived norms or making norms more salient difficult to disentangle.

Generally, there are three opportunities to deploy social norms in an intervention design to effect behaviour change. First, the intervention can make others' behaviour more visible or salient, hopefully correcting misperceptions that shape individuals' evaluations of the risks and benefits of the behaviour. Second, an intervention can make one's own behaviour more observable by others, such that individuals are more likely to comply with descriptive and injunctive norms for fear of sanction. Third, respected peers or opinion leaders can promote, endorse, or request the behaviour, providing a strong signal that the behaviour is normative and will garner social approval. Recognizing the substantial variation in the effects of social norms-based interventions, Theory of Normative Spectrum posits that

norms vary in their influence on behaviour along a spectrum, with the strongest norms making a behaviour obligatory and the weakest norms making a behaviour merely possible (Cislaghi and Heise 2018).

Scarcity theory and the psychology of decision-making

This chapter has presented two overarching perspectives on human behaviour that are both useful in the real world: the rational decision-making perspective and the behavioural economics perspective. Several studies conducted in recent years provide a more nuanced view on decision-making and provide additional insight on the two perspectives we have summarized so far. By studying how being in poverty affects individuals' decision-making, this work represents a bridge between the perspective that poverty affects behaviour because of pure constraints (not having sufficient income to access healthcare, for example) and the perspective that heuristics and biases in decision-making explain behaviour (people are present-biased in their decision-making, for example). Lab and field experiments have shown that in fact, the very condition of being poor–facing scarcity–gives rise to various features of decision-making central to behavioural economic theory such as present bias and limited attention.

One study has shown that poverty leads to increased temporal discounting—the degree to which future costs and benefits are devalued—and also to greater present-biased decision-making (Haushofer and Fehr 2014). Using data from a randomized trial in Kenya in which some households received large cash transfers, this study was able to examine differences in time discounting and risk-taking behaviour among individuals who did and did not face extreme poverty. This study and others have also shown that poverty increases stress (Haushofer and Fehr 2014) and impedes cognitive function (Mani et al. 2013). By reducing mental bandwidth (Mani et al. 2013), poverty makes it more difficult for individuals to undertake actions that are beneficial in the long-term but lack clear short-term benefit. These and other studies revealing the psychological consequences of poverty have important implications for many domains of health in LMICs and for antipoverty programmes more generally. If poverty contributes to limited attention, cognitive capacity, and worse decision-making regarding health and other future-oriented

behaviours, then programmes and policies should at the very least reduce the cognitive burdens associated with processing health information or consider using interventions such as incentives that address present-biased decision-making. Interventions such as reminders to counter the effects of limited attention also become more necessary for some behaviours such as medication adherence.

An even stronger implication of research on the psychology of poverty is that interventions such as unconditional cash transfers may have a broad array of favourable consequences for decision-making and for health outcomes. Rather than merely bringing households out of poverty and eliminating resource constraints that limit consumption expenditures, cash transfer programme can also promote forward-looking decision-making. Recent years have seen growing consideration as well as implementation of unconditional cash transfer interventions in LMICs, sometimes under the rubric of universal basic income policies. Several evaluations of unconditional cash transfer programmes have shown largely positive effects on a broad array of health and economic outcomes. One randomized trial examined the effects of unconditional cash transfers of $400-$1,500 provided by a non-governmental organization, GiveDirectly, to rural Kenyan households and found large increases in consumption, psychological well-being, and asset holdings (Haushofer and Shapiro 2016). Several other studies have examined the effects of unconditional cash transfers provided by governments to low-income households. These studies have documented improvements in sexual and reproductive health outcomes in addition to changes in other forms of decision-making.

Moving the field forward

Applying behavioural economics insights to global health programmes offers great potential to address the ‘last mile’ behavioural challenges to achieving better health outcomes. Researchers and practitioners from several disciplines have generated promising results in diverse settings through focused laboratory or basic science studies and through field experiments. Two important questions have been answered in the strong affirmative: first, can behavioural economics and behavioural science more broadly move the needle on behaviour change that is relevant for global

health? Yes—we hope this chapter is persuasive in identifying successful interventions that leverage behavioural science to boost or supercharge existing health interventions. Second, is there continuing demand among health ministries, funders, and bilateral and multilateral development agencies for bringing a behavioural economics lens to intervention and programme development? We say ‘yes’ to this as well: a quick search of ‘behavioural insights’ and ‘health behaviour change’ will yield a rich array of initiatives in many countries, at all levels and at diverse scales, that are focused on tackling persistent global health challenges with the behavioural economics toolkit.

That said, practitioners and researchers alike have many outstanding questions about how to incorporate behavioural economics into their global health work. Similarly, funders and government units must set strategic priorities and allocate budgets. We argue that the field is poised at a unique moment to take stock of progress and chart a path for the coming decade that will enhance and amplify this work further. As a starting point, we propose this focused list of recommendations for opportunities to move this exciting work forward:

Continue to support and conduct rigorous field trials of promising interventions. As we write this chapter, a team of economists has just won the 2019 Nobel Prize in Economics for their efforts to use randomized controlled trials to test policies and interventions to alleviate global poverty and improve well-being. We will always need efficacy and effectiveness trials to answer the crucial 'Did it work?' question for interventions informed by behavioural insights. While health ministries and communities are understandably skeptical and sometimes reluctant to randomize interventions to participants and may not view evaluation investments as their highest priority, we need to ensure that we scale the interventions that work and abandon or revise those that don't. While it's important of course to learn about average treatment effects, heterogeneous treatment effects are also vital to answer crucial secondary questions: 'for which subgroups, settings, and behaviours did this intervention work best?' It is harder to power, fund, and carry out studies that pre-specify subgroup analyses, but we will learn faster how to target and tailor our behaviourally informed interventions if we do.

Build capacity in behavioural science across sectors and disciplines. In our experience, frontline health programme managers and government ministry staff are eager to learn and apply behavioural science. Few will receive formal training in the theory or practice of behavioural economics, but focused capacity-building and 'on the job' training can infuse a behavioural science perspective vertically and horizontally across work units responsible for health programmes and outcomes. This capacity-building can be layered on to existing topical conferences, funder convenings, and other high-profile efforts for maximum leverage. While degree programmes in applied behavioural science are proliferating globally, there is also enormous scope for certifications, short courses, institutes, and initiatives that allow frontline staff and managers to get up to speed rapidly.

Invite implementation science perspectives to the table. There is an extensive literature documenting the behavioural science evidence from focused efficacy and effectiveness trials. Less studied (and less resourced) are efforts to systematically study the implementation and scaling of the evidence-based interventions that emerge from those trials. Implementation science encourages us to investigate the strategies that enable behavioural economics interventions to successfully and sustainably scale. More work is needed on how to bake this perspective into existing approaches and

initiatives. For example, a key strategy to implement a behaviourally informed intervention may be to build stakeholder demand and increase stakeholders' positive appraisal of behavioural economic or nudge approaches. Empirical work that formulates and tests implementation strategies of this type is sorely needed (Trujillo et al. 2014).

Consider a Nudge Unit or Behavioural Insights Team approach. The formation of units embedded within government agencies or consulted by government agencies and other health sector practitioners can foster real-world application of behavioural economics. These units, sometimes referred to as Behavioural Insights Teams or Nudge Units, typically comprise behavioural science experts who are tasked with actively engaging practitioners and jointly developing and testing low-cost interventions to improve outcomes. Governments in the United Kingdom and United States have formed behavioural insights teams to improve the performance of government agencies (Halpern and Sanders 2016). Several health systems have also established such teams to improve healthcare delivery (Patel et al. 2018). These units work best when members of the health system—from leaders to frontline healthcare workers—have opportunities to obtain basic training in behavioural insights and intervention design and can propose and prototype nudges and other interventions. Members of the nudge units themselves can further guide intervention development.

Bring behavioural insights to additional health domains in LMICs. Many of the most pressing challenges in global health remain understudied from a behavioural economics perspective. A glaring case of this is the growing burden of NCDs is in LMICs. Relatively few studies or programmes have applied behavioural insights to promote the behaviour change that is needed to curb the rise of NCDs. In contrast, behavioural economics applications to health in the United States and other high-income countries have long focused on behaviours such as smoking cessation and physical activity. Just as behavioural economics research and practice has furthered our understanding of how to control HIV/AIDS and other infectious diseases in low-income settings, we see considerable potential for similar approaches in the NCD space. Another important contributor to global health outcomes that has been relatively neglected by behavioural economics researchers is the supply side of healthcare. The vast majority of nudge studies conducted and nudge interventions that have been scaled-up have addressed the

demand side of health, which is to say they have focused on modifying health behaviours of patients or individuals in the general population. Provider behaviour can and should equally be a target of interventions that use behavioural economics insights.

Applying behavioural economics in isolation will not magically solve the persistent global health challenges faced by LMICs. Rather than a panacea, it is instead a promising approach that warrants further consideration and testing. No simple nudge will remove structural barriers to health behaviour change, such as limited access to healthcare or lack of affordability. While many successful behavioural interventions have been targeted at health providers, behavioural insights are not an obvious or easy path to fixing supply-side issues as well. In its most successful application, behavioural economics offers straightforward ways to boost or supercharge existing systems or interventions to promote better take up, improve engagement, reduce procrastination, or eliminate hassle factors. In the compelling example given of offering lentils and a metal plate set to parents who vaccinated their children in India, note that the other key intervention in that study was guaranteeing that vaccination camps would be functional and reliable. It is unlikely (though not tested in that study) that the incentives alone in the absence of guaranteed vaccination camps could have boosted coverage rates as much as they did.

While this same study had a substantial effect on vaccination, many behavioural interventions will move the needle by a fairly small amount. This increases the urgency to design low-cost, light-touch interventions, and to deploy them in settings where a small effect size is still clinically or programmatically relevant if sustained. The ‘behavioural revolution’ asks us to bring a simple but powerful perspective to existing health behaviour change programmes and initiatives. If we can pay careful attention to how people actually think and behave (vs. how we hope they might optimally behave), and recognize the constraints on cognitive resources, attention span, self-control, and future orientation that poverty imposes, we can design, test, and scale interventions that will help individuals meet their health goals, and generate sustained improvements in population health and lifespan.

Governance and management of public health programmes

Zhiyuan Hou and Na He

Introduction

Public health programmes are diverse in scale, coverage, and complexity. They may be organized by local organizations, non-government organizations (NGOs), regional or national governments, and even involve globally (Yeoh 2015). Due to their diversity and complexity, governance and management of public health programmes become very important, and are essential to the health system performance and health outcomes (Lauer 2001; WHO 2002a, 2007; Mills et al. 2006; Institute on Governance 2011). The literature has increasingly showed the strong association between governance and health system performance (Olafsdottir 2012), and effective governance can achieve the goals of public health organizations or programmes (Institute on Governance 2011). The cross-country studies by both the World Bank and World Health Organization (WHO) found strong causal relationships between better governance and health outcomes (Kaufmann et al. 1999; Lauer 2001; Mills et al. 2006). In contrast, Gupta et al. (2000) found that corruption indicators were negatively associated with child and infant mortality, immunization coverage, and low-birthweight. Furthermore, Wagstaff and Claeson (2004) showed that health spending reduced child mortalities only in countries with high governance measures, and more spending in countries with medium and low governance measures would not reduce child mortality. The association between governance and health can operate at multiple domains, including the broader governance environment, health and general public policies, and the effectiveness of organizations within the health system (Savedoff 2011).

Worldwide, health systems work well in some countries but not well in others. To answer the question for health system performance, the WHO

builds a framework of strengthening health systems to improve health outcomes, which includes six function components: governance and leadership, healthcare financing, health workforce, medicines and technologies, information and research, and service delivery (WHO 2007). In the WHO health systems framework, governance and leadership is the central component to make the other function components effectively work together. Governance in the health system refers to 'a wide range of steering and rule-making related functions carried out by governments/decisions makers as they seek to achieve national health policy objectives that are conducive to Universal Health Coverage (UHC)' (WHO 2007). Good governance can enable the effective use of healthcare finances, health workforce, medicines and technologies, information, and research to deliver better health services and outcomes (WHO 2016). Overall, effective governance is central to improve the health systems performance and achieve UHC (WHO 2016).

As the world become increasingly globalized, public health programmes are sometimes cross-border, and their governance also need to be considered at the global level. Development assistance for health has globally increased from US$7.2 billion in 1990 to US$36.4 billion in 2015 (Dieleman et al. 2016). Funds for these development assistance programmes are increasingly distributed through NGOs and bilateral assistance to governments instead of the traditional United Nations (UN) agencies. Although development assistance for health increased quickly, their effects depend on the quality of local governance and policies, especially in the resource constrained settings (Fryatt et al. 2017). On one side, many international donors question whether these development assistance programmes can reap benefits of improved health services and outcomes. On the other side, these global programmes may attract health workforce to leave local health systems, conflict with the goals of local health systems, and distort the local health priorities (Yeoh 2015). These may lead to negative effects on local health systems. Therefore, global health governance is necessary to address these problems at the global level. Coronavirus Disease 2019 (COVID-19) spread across the world in 2020, which emphasis on the emergence of strengthening health governance in the global context (Phelan et al. 2020).

In this chapter, we will discuss the following sections. First, we introduce the concepts of governance, health governance, and global health governance. Second, we introduce governance theories and a framework of

health governance system, covering the actors, tools, and levels of health governance. Third, we describe in detail three governing actors—government, civil society, and private sector—and their roles in health governance. Fourth, tools of health governance are introduced to carry out the health governance functions and enable relationships among actors. Fifth, we discuss four levels of health governance: supranational, national, organization, and programme. Sixth, we summarize the assessment frameworks of health governance. Finally, we take cases for better understanding health governance.

Concepts of governance, health governance, and global health governance

The concept of governance has evolved in the changing context of government and society. Originally, governance is described as 'the act or manner of governing, of extending control or authority over the actions of subjects; a system of regulations' in the *Oxford English Dictionary.*

In the domain of health, WHO first defined governance as 'stewardship' which refers to 'the careful and responsible management of the well-being of the population' (WHO 2000). This definition clarifies the importance of health governance and its role in health system and population health (Mikkelsen-Lopez et al. 2011). However, because of incoherent nomenclature and the changing context, no conceptual agreement on health governance has been reached (Kickbusch and Gleicher 2012).

The United Nations Development Programme (UNDP), defines governance as 'the exercise of political, economic administrative authority of a country's affairs at all levels' (UNDP 1997). This definition reveals that governance consists of the complex mechanisms, processes, and institutions through which citizens and organizations articulate their interests and rights. And it identifies the political and economic nature of social life, and the roles and interdependencies of the society, such as the government, private sector, and civil society. Dodgson and his colleagues consider health governance as ''the actions and means adopted by a society to organize itself in the promotion and protection of the health of its population' (Dodgson et al. 2002). WHO refines health governance as 'involves ensuring that strategic policy frameworks exist and are combined with effective oversight,

coalition building, regulation, attention to system-design and accountability' (WHO 2007). It characterizes the health governance as a set of processes formally or informally applied to distribute accountability among actors of a health system (Brinkerhoff and Bossert 2008). These definitions adapt a system perspective to understand the mechanisms in government, the private sector, and civil society, their complex nature and relationships, and how they influence health outcomes (Yeoh 2015).

More recently, the necessity of strengthening health governance at the global level has been increasingly discussed due to a series of globalizing challenges. The response to global health challenges has become fragmented and ineffective without global leadership. Global health governance is then defined as 'the action and means adopted by a society to promote collective action and deliver collective solutions in the pursuit of common goals' (Dodgson et al. 2002). This definition admits the whole range of cooperation in global society, from informal arrangements and agreements by communities to the formalized rules and procedures institutionalized in governments. This definition also pays attention to the equal roles of the governments, private sectors, and civil society in global health governance, because health governance has become beyond the scopes of governments (Yeoh 2015). A single emphasis on the government role in health governance, neglecting the important roles of civil society and the private sector in health system, will undermine the governance capacity (Ollila 2005; Renukumar n.d.). Contributions from all governing actors for the collective actions in the pursuit of common goals are critically necessary in health governance.

Theory and framework of health governance system

Theory of governance

There are two main theories to approach systems-level governance: principal-agent theory from the economics discipline, and theory of network governance from the public administration discipline (Greer et al. 2016). Principal-agent theory focuses on market competition, contracting, outsourcing, and incentives; and the theory of network governance emphasizes the power and effectiveness of networks, cooperation, and partnership. Both theories aim to address the interactions between

organizations in governance system, including the shifting boundaries, unclear authority, and complexity of coordination, and have been widely used in health system governance.

Principal-agent theory. Principal-agent theory illustrates the contract relationship between principals and agents. The principle hires the agent to undertake an action and pays in some certain forms such as incentives. Agents usually have more relevant information on the service than principals, thus enables them with an advantage of 'information asymmetry' to favour their own interests at the cost of the principal. Another feature of the principal-agent theory is that the principal does not have full control over the agent and possess only partial information about the service behaviour of the agent (Stoker 1998). Because of the distinctive features, moral hazard, and adverse selection problems may appear. The agent tends to take its own preferred actions and hide some information the principal needs to make decisions for the agent's interest (Gailmard 2012). Taking account of the uncertainty and complexity of behavioural outcomes of the agent, principal-agent theory is used as an approach to analyse different actors in governance systems.

Health systems are featured as purchaser–provider splits, more use of markets and contracts to encourage private sector participation, greater management autonomy for providers, emphasis on procedure control and regulation, and outsourcing ancillary functions. In health system, there are various actors—policymakers, healthcare providers and citizens, and these actors and relationships constitute the health governance system. Principal-agent theory can be used to understand these actors and relationships, and various governance frameworks for health systems are intensively developed based on principal-agent theory (Brinkerhoff and Bossert 2014). However, the relationships are mostly more about fiduciary than agency, especially for government and policymakers, and government accountability has long been questioned. Therefore, the approach to analyse the relationships among organizations should be to in the round- in their interconnections, dependencies, and accountabilities. Despite widely used in health governance, the problem with principal-agent theory is that the complex web of relationships is oversimplified to principal-agent relationship.

Theory of network governance. Theory of network governance aims to address the complexity that principal-agent theory neglects and provide a solution to coordination dilemmas among multisector actors, in which

clients, providers, and producers are linked together as co-producers. Network governance focuses on interdependence among organizations, interactions among network members, and management joint responsibilities (Rhodes 1996). Fixed organizational boundaries and roles are replaced by a new rationality of the shared aims and culture (Considine and Lewis 2003). Sørensen and Torfing (2007) defined 'governance network' as a number of interdependent and autonomous actors who interact through negotiations under a relatively self-regulating institutionalized framework and contribute to the production of public purpose.

Network governance is promoted for the potential contribution to efficient governance because of its following distinctive features. First, network governance comes with a potential for identifying early stage problems and making proactive adjustment. Besides, aggregation of information, knowledge, or opinions help qualify decisions or consensus building. Finally, networks of organizations greatly reduce the risk of implementation resistance (Sørensen and Torfing 2007). While network governance is advocated to promote cooperation among multi-actor systems, there are two empirical problems with regarding governance solely as partnerships and networks. On one hand, networks and partnerships can be everywhere and nowhere, and so finding networks that actually govern and align organizations and forces can be hard. On the other hand, network governance does not simply displace hierarchy and law. In some situations, it seems that networks function best under the shadow of hierarchy to oblige them with legal force. Cross-sectional legislation could offer a general guidance for network governance in activation. However, legislation and hierarchy pose a risk to the autonomy and flexibility of the network. Still, the questions regarding decision-making and accountability can hardly be addressed by legislation (Saikku and Karjalainen 2012). The merits and problems of network governance mean that they are unlikely to be the sole basis for health system governance.

Framework of a health governance system

A population's health is determined together by individual factors, social and community networks, and social, economic, cultural, and environmental conditions (Commission on Social Determinants of Health 2008). The most important determinants of health are from other sectors, rather than the

health sector itself. Most health challenges originate beyond healthcare, but they also depend on the global processes that drive disease outbreaks, food insecurity, climate change, urbanization, and economic inequity. This calls for a whole-of-society governance approach for health. The governments, the private sectors, communities, and citizens are required to increasingly engage in governance for health. Thus, health governance involves a wide range of actors at the level of the governments, civil society, and private sectors.

In health governance system, the government, private sector, and civil society are the governing triangle (actors), and they are seeking public health collectively (Abimbola 2020). Each governing actor has its structures, roles in governance, governing tools, and mechanisms for interactions within and between the actors. They play health governance functions at four levels to pursue health goals: the supranational or national or organizational or programme levels. Overall, the three governing actors (triangle), their governance functions and mechanisms, and governance relationship, form a health governance system and a whole-of-society governance approach for health. A framework for health governance system can help to understand the whole-of-society governance approach for health, covering the governing actors, governance mechanisms and tools, their governance relationship, and governance at different levels (Yeoh 2015). Figure 6.8.1 summarized this framework for health governance system.

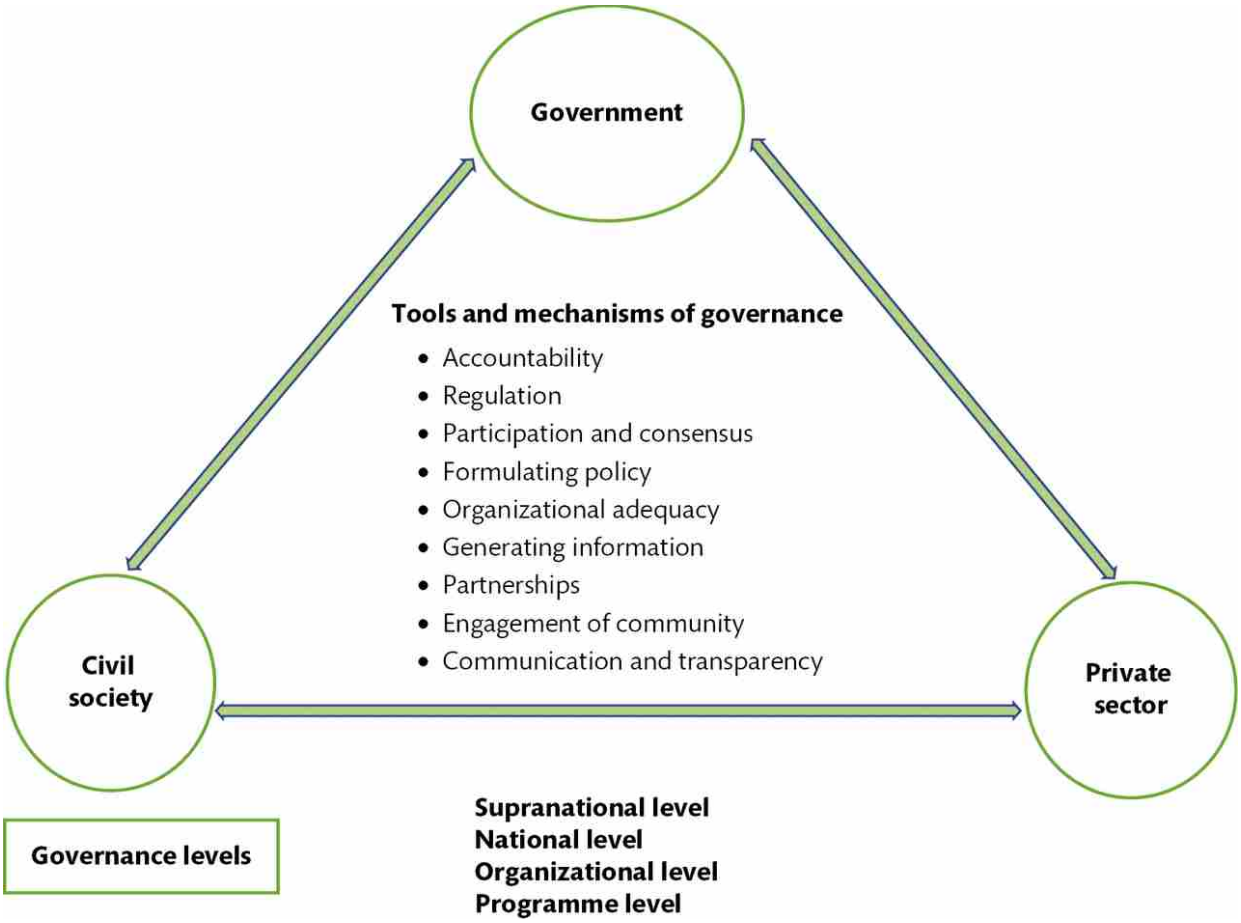

Fig. 6.8.1 Framework for a health governance system.

WHO proposed effective health system governance to achieve UHC, and the governing triangle can be the government, health service providers, and the citizen or civil society. The governing triangle is linked through the governance relationships, mainly principal-agent relationships (Brinkerhoff and Bossert 2014). They make or change governance rules, and these governance rules in turn influence each other's actions and relations (Abimbola 2020). In the relationship between civil society and the government, civil society acts as the principal to express health needs and preferences to the government, and the government works as the agent to respond to these needs and preferences. In the governance relationships between the government and providers, health policymakers are principals setting up objectives and standards, providing resources, and conducting overseeing providers as their agents. In exchange for the resources, providers take health service delivery activities to meet the requirement of policymakers. In the governance relationships between the civil society and

providers, civil society expresses health services needs to providers, who provide health services in turn. But this relationship is challenged by information asymmetries, capacity gaps, and moral hazard between the civil society and providers. Theories of principal-agent and network governance can help to address these challenges and complexity of networks, and better understand health governance at system level (Greer et al. 2016).
According to the health governance system framework, the following sections will introduce each governing actor and its role in governance, the governance tools available, and the levels of governance.

Actors and roles in health governance

Health governance system is the triangle of government, private sector, and civil society. This section will focus on each of governing triangle and its roles in health governance (Table 6.8.1).

Table 6.8.1 Actors and roles in health governance

Actors	Roles and functions in health governance
Government	Regulation Policy development Resource stewardship Coordination and partnership
Private sector	Health services provision Financing Health workforce training Regulation
Civil society	Shaping policies and standards Health services provision Strengthening the health system Community mobilization

Government and its roles in health governance

The government is the leading actor of national health governance, and the key actor of other levels of health governance. There are two forms of

government: federal and unitary, which determine the form of health governance. The federal government owns all the basic powers, but powers are further distributed to local governments of states and authorities, which is decentralized in nature (Elazar 1997). The federal government is not essentially more powerful than those of its states, and usually, unilaterally assigning itself new powers cannot success without the process of constitutional amendment (Fisch 2018). In contrast, the key principle in unitary government is the hierarchical and efficient control and organization of power (Elazar 1997). The federal and unitary forms of governments have their own strengths and weaknesses. Federal government allows the promotion of diversity, and unitary government creates a sense of belongings and uniformity. In addition, decentralization of power accommodates variations suitable for regional problems, while unitary governments make laws only by a single government, and enforce throughout the whole nation without territorial distinction. Federalism increases political participation for different regions and allows states to decide policies reflecting their own needs, while for unitary government, there is less regional level political participation. Besides, federalism may encounter obstructs when acting on national issues due to various interests of states, whereas centralized unitary government determines all regional, national, and international affairs without any disruption (Perera 2020).

In the health field, the federal government may have the financing responsibility while delivering and regulating health services may be the provincial or local responsibility. However, various responsibilities may not be clearly distributed across different levels of government. This ambiguity creates challenges for the coordination of public health responses among different levels of government, and gaps and duplications in carrying out public health responsibilities become potential problems (Office of the Auditor General of Canada 1999). In unitary government, coordination of public health responses and conflicts across different levels of government does not have the challenges of federal forms, while there may be the organizational and managerial problems (Yeoh 2015).

The government plays the dominant role in health governance system no matter of federal or unitary government. The traditional roles of government include regulation, policy development, and resource stewardship (Carlson et al. 2015). Since more actors increasingly engage in health governance, the role of government is expanding and it should also play a role of fostering

coherence, collaboration, and partnership, with civil society and the private sector (St-Pierre 2008).

Regulation. The regulation, as all mechanisms of intentional and unintentional control, sets up the roles, responsibilities, obligations, and functions of the governing body, health officer, and agency staff by the laws and rules (Saltman and Russe 2002). Powers of regulations accrue to the three branches of government, the executive, legislative, and judicial, and can be in forms of administrative decree, legislation, and judicial orders. Many important public health policies are enacted in laws. Regulations on drugs and biological products seek to protect the public, ensuring the safety and quality of these products. The regulatory function may be administered by the government directly or a public agency or the professionals.

Policy development. The development of policies aims to protect, promote, and improve public health. The government should develop the evidence-based policies that support public health agency goals; develop and regularly updating vision, mission, goals, measurable outcomes, and values statements; set short- and long-term priorities and strategic plans; regularly evaluate public health policies to ensure that they are based on the best available evidence for public health practice (Carlson et al. 2015).

Resource stewardship. Resource stewardship aims to assure the availability of adequate resources (legal, financial, human, technological and material) to perform public health services, including resource collection and allocation (Carlson et al. 2015). First, taxation is one way of resource collection, and providing tax incentives or disincentives would influence targeted behaviours (Deber et al. 2004). Provision of tax exemptions for NGOs and charitable foundations has encouraged their growths in civil society, many of whom are engaged in health services. Tax disincentives, such as tobacco tax, have effectively discouraged the smoking behaviour. Second, resource allocation can be cash or in-kind support, and can address the inequity across regions. For examples, contracts and direct payments to NGOs to operate public health programmes, or providing subsidies for vaccines to encourage vaccination uptake.

Coordination and partnership. In modern society, empowered citizens demand more information and influence, and a broad consensus of stakeholders should be achieved (Jakubowski and Saltman 2013). There are strong needs for improved central coordination across stakeholders and decentralizing information and decision-making to citizens. The government

should build and strengthen community partnerships through education and engagement to ensure the collaboration of all relevant stakeholders in promoting and protecting the community's health. A flexible partnership mechanism can be networks of government agencies with the private sector and civil society, for example public–private partnership.

The private sector and its roles in health governance

The private sector discussed in this section refers to all the privately-owned groups and organizations participating in health governance: profit and not-for-profit, formal and informal, domestic and international (Clarke et al. 2019). In most countries, the private sector is generally large and heterogeneous, ranging from medicine stores and individual clinical practitioners to corporate hospital chains and international private insurers (Mackintosh et al. 2016). They play a very important role in health governance.

Almost all countries have mixed health systems, with health products and services provided by both the public and private sectors. However, the private sector may live in the different positions across countries (Mackintosh et al. 2016). The private sector can be dominant in some countries' health systems, such as India and Nigeria, or be complementary in countries like Sri Lanka and Thailand. The private sector may be at the top of a stratified health system in countries like Argentina and South Africa, or the stratified private sectors are shaped by low incomes and public sector characteristics in some African countries. There is also the highly commercialized public sector in some countries.

A large proportion of health expenditure goes to the private sector (Forsberg and Montagu 2014), which reaches nearly 50% in low- and middle-income countries (WHO 2011). The private sector has become an essential actor with abundant resources and powerful influences to deal with health issues. The private sector not only provides lots of jobs but also influences public policy in governance system. They are usually diverse in organization forms (Stallworthy et al. 2014), which allow them rapid response to the diversified demand from people and changing environments. Although the private sector has these advantages, challenges surrounding conflicts of interests are ubiquitous, and there is also a lack of conceptual clarity about the role of the private sector in health systems. The other governing actors engaging the

private sector in healthcare may have different understandings of key terms and concepts of the private sector (WHO 2018).

These resource and characteristics enable the private sector to play multiple roles in the health governance system. These governing roles mainly include services provision, financing, training, and regulations. The provision of health services and products from the private sector occupies an important position in the health system. A review of data from six countries displays a significant trend of greater use of private sector to deliver care in Asia over the last decade (Forsberg and Montagu 2014). With the rapid development of the financing role, the private sector has become a necessary condition for participation in the social insurance programme in some countries such as America. Private corporations and foundations also run many public health programmes around the world, which train health workforce, create job opportunities, and bring the latest technology to local health systems. The private sector has been also increasingly cooperating and authorized by the government for regulations. The Open Working Group Proposal for Sustainable Development emphasizes that the implementation of Sustainable Development Goals depends on global partnerships with the active engagement of governments, civil society, and the private sector (Kunkle et al. 2016). In countries receiving large development assistance from international private organizations, private donors have a strong influence on policymaking and priorities setting of local health systems. Moreover, the private sector and the public sector are influenced by each other (Mackintosh et al. 2016). Public–private partnership therefore creates an integral part of government policies which enables mobilizing and ensuring efficient use of resources, promoting improved delivery systems, and developing localized models (Stallworthy et al. 2014).

Civil society and its roles in health governance

In the absence of agreed definition, civil society is generally understood as the social arena existing between the state and the individual or household to empower social individuals and groups to be involved in the decision-making process and to build platforms for civil actions, which theoretically comprises a diversity of spaces, actors, and institutional forms varying in their degree of formality, autonomy and power (WHO 2001). Civil society creates the space for collective actions and practices based on common

purposes, interests, and values, which is generally believed to be non-state, not-for-profit, and voluntary (The Commission on Social Determinants of Health 2007). Civil society organizations (CSOs) usually include philanthropic foundations, labour unions, non-governmental organizations, business associations, trade unions, professional associations, academic institutions, think tanks, religious groups and organizations, cooperatives and community groups, social movements, lobby groups, women's networks, youth associations, relief organizations, coalitions and advocacy groups (WHO 2002b). Thus, there exists numerous differentiations among civil society actors that primarily determine the heterogeneous and complex nature of it, as well as its various ways of operation (Commission on Social Determinants of Health 2007). In some circumstances, the boundaries between civil society and government or commercial actors can become blurred due to the state or market links to some CSOs (Commission on Social Determinants of Health 2007).

Despite the complexity and heterogeneity of civil society, it plays a prominent role in health governance, which includes four aspects: shaping policies and standards; health services provision; strengthening the health system; community mobilization.

Shaping policies and standards. Civil society has engaged in developing health policies and standards through advocating the stakeholders and the public, creating dialogues with policymakers, or promote the legalization of health policies (WHO 2001). Civil society has mastered and applied the skills of communicating with governments and stakeholders, such as using the clear and strong languages the policymakers preferred, which remarkably promotes their engagements in health policymaking. The policies and standards in which the civil society has been involved cover various health issues such as prices and access to drugs, breast milk substitutes, tobacco control, environment, and policies or standards in debates (WHO 2001). Besides, civil society also provides new health evidences to policymakers to support or oppose some health policies and standards through conducting or supporting a great number of researches (Lencucha et al. 2011). Civil society enables the participation of communities in health policymaking, and also represents the voices and perspectives of some excluded or marginalized social groups.

Health services provision. Civil society has had a long history of providing health services and has become more involved in recent years. Civil society

provides services to targeted population in response to their health needs and adapted to local conditions (WHO 2002b). Civil society focuses on the vulnerable or disadvantaged groups poorly served by government health facilities and provides more cost-effective health services to them (WHO 2001). Civil society also assists governments in major diseases control programmes, treatment campaigns, and health resources distribution, and is playing a more effective role in facilitating the interaction among governments, communities, and clients. Besides, civil society supplies a range of technical supports for health services provision. It is worth noting that civil society carries competitive advantages in health services provision when they own the access to health resources that is not available to government.

Strengthening the health system. There is an increasing number of CSOs contributing to support governments to strengthen local health systems. In many developing countries, CSOs have provided assistances and shared expertise to support Ministries of Health (MOH) to strengthen health systems at all levels (Barbazza and Tello 2014). To build strong partnerships with local MOHs, many CSOs have tailored their actions to the goals and strategic plans of local authorities. Meanwhile, CSOs also focus on the communication, transparency, and flexibility when administrating and implementing joint programmes with local authorities for health systems strengthening. Health workforce and infrastructure are the two key areas that civil society have engaged in for strengthening health system.

Community mobilization. CSOs are effective channels of communications between individuals and business and the state, and promote the participation of community on health campaigns and actions (Van der Rijt and Pang Pangestu 2015). Civil society raises the community preferences in public resources allocation and management that better reflect community needs.

Tools of health governance

Health governance must be equipped with applicable tools to enable the governance function and to steer the health system toward defined goals. Tools to govern are central to carrying out the health governance function and enabling relationships among actors. Tools of governance can be classified into nine governance dimensions: (1) Control mechanisms and

accountability; (2) Regulation; (3) Participation of stakeholder and consensus in decision-making; (4) Formulating policy and strategic direction; (5) Organizational adequacy or system design (capacity building); (6) Generating information and intelligence; (7) Partnerships, coordination, and collaboration; (8) Engagement of community; (9) Communication and transparency (Barbazza and Tello 2014). The first six dimensions mainly involve to play the subfunction of health governance, and the last three dimensions involve to enable relationships or networks among actors. Table 6.8.2 described the dimensions and tools of health governance.

Table 6.8.2 Dimensions and tools of health governance

Dimensions	Tools of health governance
Control mechanisms and accountability	• Governance structure • Fair competitive elections, systems of judicial redress, procedures to combat corruption • Regular internal/external audits • Performance-based contracts
Regulation	• Laws and declarations • Rules, procedures, decrees • Codes of conduct • Performance standards, accreditation, licensing/certification • Statutory bodies (e.g. national regulatory agency)
Participation of stakeholder and consensus in decision-making	• Sector-wide approaches • Consensus conferences • Forma consultations in drafting legislation • Stakeholder identification and voice • User-friendly complaint system • National health forums • Open meetings, public workshops, national forums, citizen advisory committees, citizen juries • Satisfaction surveys, feedback, responsiveness
Formulating policy and strategic direction	• National health plan • National targets, goals, and performance measures • Multiyear strategic plan • Policies, operational guidelines, training manuals, protocols • Medium-term expenditure frameworks and national health accounts • Targets-and priority-setting techniques

Dimensions	Tools of health governance
Organizational adequacy or system design (capacity building)	• Implementation or annual operational plan • Monitoring and evaluation plan • Training/personnel manuals • Mission/vision statement, organizational chart • On-the-spot training measures • Peer-to-peer learning programmes
Generating information and intelligence	• Project evaluation • Conducting research • Commissioned reports by independent researchers • Interministerial fact-finding commissions or taskforce • Parliamentary investigations • Periodic audits, public expenditure, and performance reviews • Internationally recognized tools for conducting a situation analysis • Geographic information systems, or health needs assessment
Partnerships, coordination, and collaboration	• Interministerial and interdepartmental committees • Professional advisory committees • Public–private task force • Partnerships with civil society or agencies • Integrated budgets and accounting, co-funding arrangements, or earmarked grants • Cross-cutting information education systems • Common workforce training, qualifications, support, and advice • Ad-hoc, initiative-specific committees
Community engagement	• Outreach, consult, involve, collaborate, share leadership
Communication and transparency	• Watch dog committees • Releasing financial or performance information to providers and the public • Inspectorates, fact-finding commissions • Opportunities for public consultation or feedback • Mass media • Conflict-of-interest boards

Reproduced from Barbazza E, Tello JE. (2014). A review of health governance: definitions, dimensions and tools to govern. *Health Policy*, 116(1), 1–11 with permission from Elsevier.

Accountability means that decision-makers in government, the private sector, and CSOs involved in health are accountable to the public, as well as to institutional stakeholders (Siddiqi et al. 2009). Accountability tools include governance structure, grievance redress mechanisms, regular internal/external audits, and performance-based contracts. Regulation means that legal frameworks pertaining to health should be fair and enforced impartially to support strategies, goals, and priorities. Regulation tools involve legislative process; interpretation of legislation to regulation and policy; enforcement of laws, and regulations (Siddiqi et al. 2009).

Participation and consensus involve generating dialogue and receiving feedback among various actors (Barbazza and Tello 2014). The participation and consensus tools include sector-wide approaches, national health forums, open meetings, citizen juries, and consensus conferences, among health governance actors.

Every organizations should formulate policy and strategic direction, and ensure organization adequacy or the appropriateness of the system design, through capacity building and various training programmes (Barbazza and Tello 2014). Intelligence and information are essential to provide evidence for informed decisions that influences the behaviour of different interest groups. Tools to generate intelligence and information include project evaluation, conducting research, public expenditure, and performance reviews.

Partnerships, coordination, and collaboration should be established across government, civil society, and the private sector, to facilitate action which improves health and to generate support for health policies (Barbazza and Tello 2014). Coordination can enable interactions that are supportive of the joint management of activities through formal processes, whereas collaboration is established on shared values and goals but with more informal interaction.

Community engagement is the process of working collaboratively with and through groups of people affiliated by geographic proximity, special interest, or similar situations to address issues affecting public health (CDC 1997). It can achieve social mobilization to recruit, mobilize, and motivate individuals and groups to actively participate. Communication with the public is intended to simply allow dialogue and improve the exchange of information,

and the free flow of information can improve transparency. And tools in the communication and transparency dimension include the releasing financial or performance information to providers and the public, mass media, and opportunities for public consultation or feedback (Demand for Good Governance Team 2010).

Levels of health governance

Health governance occurs at four levels: (1) supranational or global level; (2) national or local levels; (3) organization level; (4) programme level. The governing actors can play health governance functions at each of the levels to collectively pursue health goals, and the mechanisms and governance at each level need to be examined. This section will introduce the different levels of health governance: supranational health governance, national health governance, governance of public health organizations, and management of public health programmes.

Supranational health governance

Health governance at supranational level is distinct from governance at other levels: there is no overarching political authority at the global level (Frenk and Moon 2013). The traditional tools for health governance at national level, such like democratic decision-making procedure or regular enforcement of laws and regulations, are absent at the global level (Lee and Kamradt-Scott 2014). The global nature of health determinants restricts the capacity of national governments to address them on their own, and therefore the international and global strategies are required. The global trends, such like changing population demographics, financial uncertainty, deepening social inequity, outbreak of new infectious diseases, further call for the effectively collective action, agreement and enforcement on rules, and achievement of policy coherence to address global health affairs (McInnes et al. 2012). Therefore, more actors gradually join in the actions of global health governance to improve health, along with the rules and norms governing their interactions in the new reality of pluralism (Szlezák et al. 2010).

The primary actors involving in the supranational health governance include: United Nations agencies; national governments; multilateral development

banks; global health initiatives; philanthropic organizations; and CSOs (Frenk and Moon 2013; Ng and Ruger 2014). Table 6.8.3 describes the primary actors in the health governance at supranational level, and gives some examples.

Table 6.8.3 Primary actors in health governance at supranational level

Type of actors	Examples
United Nations system	World Health Organization
	United Nations Drug Control Programme
	United Nations Population Fund
National governments	Ministries of health
Multilateral development banks	World Bank
Global health initiatives	GAVI Alliance
Philanthropic organizations	Bill and Melinda Gates Foundation
Civil society organizations	International Diabetes Federation

WHO is established by UN as 'the directing and coordinating authority on international health work' (WHO 2013a). WHO is developed based on the universal membership of all recognized nation states, who play the central role in global health system to produce profound influences on a range of difference actors to enable them to contribute more effectively to the well-beings of all people (WHO 2013a). WHO operates as a scientifically grounded, technically focused institution guided by a humanitarian ethic that viewed health as central rather than basing on treaty-based value (WHO 2013a; Ng and Ruger 2014). WHO has gain great achievements during the last decades. However, there exists consensus that WHO, as the sole authority on global health, is unable to provide sufficient leadership for global health and effectively respond to vital global health threats. It is imperative for WHO to reform its architecture and framework to regain the capacity and authority on global health. Also important to the supranational health governance system are other UN multilateral agencies. The World

Bank has superior resources in health development, financing, and policy advising of the main global multilateral agenda (Ruger 2005).

The national governments are still considered as the core player to take ultimate responsibility in global health governance affairs, even in low- and middle-income countries, since they decide what is implemented domestically and internationally and provide support to organizations like WHO (Kohlmorgen 2005; Fidler 2010). Moreover, supranational health governance significantly depends on the capacity of nation states (Gostin and Mok 2009). National governments coordinate their responses to global health challenges through various mechanisms (Frenk and Moon 2013). Although rich and powerful states could set priorities in global policies and initiatives (Ng and Ruger 2014), emerging countries such as China and Brazil, increasingly engaged in global health governance through financial and technical assistances (Ruger and Ng 2010).

In addition to the well-established and long-standing actors in supranational health governance, new players present increasing engagements in supranational programmes and initiatives, producing both competition and cooperation among old actors (Kohlmorgen 2005; Fidler 2010). The Global Alliance for Vaccines and Immunization (GAVI) play a vital part in functioning global markets of health commodities for target diseases control (McColl 2008). Philanthropic organizations and CSOs potentially become the essential partners on global health activities due to their organizational flexibility, cost-effectiveness, and access to communities, especially in remote and difficult areas (Ollila 2005; Doyle and Patel 2008; Kruk 2012). The proportion of development assistance for health channelled via UN agencies and development banks has decreased, while global health initiatives, NGOs and the private sector have accounted for an increasing share of development assistance (Ravishankar et al. 2009). The significance of the changes demonstrates the fact that these UN agencies have to compete with NGOs for a share of the voluntary contributions.

The health governance at supranational level carry out three main functions to achieve health goals. The first function is to provide overall strategic direction to the global health system so that all other functions can be implemented sufficiently (Frenk and Moon 2013). The second function is to mobilize global solidarity including financial development, technical cooperation, and humanitarian assistance for achieving global agenda (Frenk and Moon 2013). The last function is to generate global public goods in a

variety of forms including research and development, standards, and guidelines, and comparative evidences and analysis (Stuckler and Mckee 2008; Frenk and Moon 2013). Good global governance for health is considered to demonstrate the following characteristics: ‘effectiveness, equity, and efficiency in achieving outcomes, as well as credibility and legitimacy in decision-making procedures’ (Koplan et al. 2009; Frenk and Moon 2013).

However, there exists three challenges that impede the global governance for health. First of all, in the absence of a clear leadership of global health, it turns to be very difficult for individual actors to achieve the sustainable agreement on their respective contributions in response to the common health threats (Koplan et al. 2009; Kickbusch 2016). Given the diversity of the challenges in global health and the growing number of actors, the regime of supranational health governance is complex and even competing when engage multiple players addressing different problems through diverse principles and processes (Stuckler and Mckee 2008; WHO 2013b). As a result, the collective actions and works at global level are hampered, which become more straitened on a circumstance of uneven distribution of health resources and the conflict interests of various actors. Second, health is increasingly influenced by the governance in other global arenas, such as trade, migration, environment, education. One major consequence of these growing recognition of the connection between health and many other areas of social and economic policy is a growing demand for intergovernmental, rather than purely technical processes, in order to reach durable and inclusive agreements (Fidler 2010). However, these policymaking arenas across multiple sectors have not sufficiently taken health concerns into account (Frenk and Moon 2013). Last, there is in the absent of definite mechanism for the accountability of non-state actors for the global impacts of their actions (Gostin and Mok 2009). The growing competition between NGOs and local service providers for funding and human resources could make the host country more difficult to provide sustainable services (Weishaar et al. 2012). It is feared that the encroachment of non-state actors will hamper the ownership and control of local actors on health governance.

As discussed, the global governance challenges will continue to weaken the capacities and efforts to deal with the complicated and critical global health issues. Therefore, it becomes urgent to take more endeavours to address the structural governance challenges. Also innovative attempts for developing

more inclusive governance for health at global level are required. The involved global actors should make new arrangements on governance to enable it more effective, accountable, and efficient. Meanwhile, more assessments on the past experiences of governance reform are needed through rigorous and systematic analysis and researches.

National health governance

The social and environmental determinants of health are mostly beyond the health sector and health policies, and thus the effect on health should be considered across sectors. Up to date, the national health governance has experienced the evolution of three waves according to the expansion of health policy—from intersectoral action, to healthy public policy, and to the Health in All Policies (Kickbusch and Gleicher 2012). The WHO defines Health in All Policies as 'an approach to public policies across sectors that systematically takes into account the health implications of decisions, seeks synergies, and avoids harmful health impacts in order to improve population health and health equity' (WHO 2014). It improves accountability of policymakers for health impacts at all levels of policymaking, and needs joint action of health and non-health sectors, of public and private actors and of citizens for public health.

WHO points out that the public health agenda has not been given the priority in some countries, and this has been attributed to insufficient political commitment, marginalization of health department in government, and the limited capacity of public health to influence policymakers (WHO 2002a). National health governance needs strong government commitment to public health, and all administrative departments of government work together to improve public health. WHO has characterized the distinguishing features of national health governance as follows: 'is multisectoral and professional; combines knowledge and action; has epidemiology at its core; is influential across all health determinants; involves public health reporting, leading to health strategy development; communicates with politicians, professionals, and the public; is influential organizationally and financially; lies at the heart of the civic society' (WHO 2002a).

The Ministry of Health assumes responsibility for public health, through the following channels: formulating health policies; developing strategies; assessing health needs and determining priorities; defining regulatory

frameworks; commissioning, monitoring, and evaluating public health programmes; and collecting and seeking health data, information, and intelligence. But many social determinants of health are not in the scope of the health ministry. All related ministries, such as ministries of finance and social security, need to collaborate to improve public health, and the cross-departmental coordination should be in place to achieve the health in all policy.

To achieve the Health in All Policies, National government should conduct the development of Health in All Policies; the ministerial leadership role in influencing other relevant government ministries; integrated policymaking mechanisms; and horizontal integration at local, provincial, national, and supranational levels. Local government should implement a national policy framework, organizational changes for coordination of providers and networks, and funding measures to enable integrated provision of public health.

In addition, horizontal mechanisms are necessary to coordinate functions and relationships among government agencies, the private sector, and civil society (Yeoh 2015). Because public engagement in decision-making is useful to design and deliver the localized health services, community governance has become an important mechanism (Pillora and McKinlay 2011). Community governance requires public engagement in consultation and decision-making processes, and strong civic leadership to mobilize communities and related stakeholders. Community governance and public engagement are particularly applicable for disadvantaged communities and to implement public health programmes.

Governance of public health organizations

The governance of organizations can be defined as ‘a set of processes and tools related to decision-making in steering the totality of institutional activity, influencing most major aspects of organizational behaviour and recognizing the complex relationships between multiple stakeholders’ (Saltman and Duran 2015). As an essential part of organization leadership, governance pertains to decision-making in an organization—what positions have authority or control over specific decisions. Governance refers to the management and controls within organizations to ensure the protection of stakeholder’s interests. Effective governance in public health organizations

is vitally important for programmes implementation to improve the human well-being.

In practice, public health organizations are diverse in the size, organizational formality, and legal incorporation status. Different public health organizations have their own governance systems and operation patterns. The legally established organizations have usually formal board structures, policies, and procedures, whereas the majority of community groups and networks have no formal governance structure and they act collectively to achieve the common objective.

Some theories are useful to guide the governance of public health organizations no matter their organizational formality. The theories are the agency theory, stewardship theory, resource dependency theory, and stakeholder theory (Chambers et al. 2012). Agency theory (Keasey et al. 1997) assumes that the owners and managers of an organization would have different interests. According to this theory, the main function of the board is to control managers through the monitoring and compliance. The boards can reduce the problems of managers pursuing their own interests or performing poorly through monitoring processes such as external audit and reporting requirements. In public health organizations, the public objectives are at risk of managers pursuing their own interests, and the board plays a key role to monitor managers and ensure their compliance in the organization objectives. Stewardship theory (Muth and Donaldson 1998) has opposite assumptions to agency theory, which assumes that managers and owners share a common agenda and work ‘side-by-side’. Hence, the main role of the board is not monitoring managers to ensure compliance or conformance, but to develop strategy to improve organizational performance. For public health organizations, the theory holds some intuitive appeal, with trustees (the public) and managers both sublimating their personal interests in pursuit of an organization’s philanthropic goal.

In addition, resource dependency theory (Pfeffer and Salancik 1978) minimizes the uncertainty caused by external environmental factors, and it considers organizations as interdependent with their environment. The main function of the board is to maintain good relations with key external stakeholders to ensure the flow of resources into and from the organization, and to help the organization respond well to external change. For public health organizations, relationships with funders, media, and various local representatives, play an important part in securing long-term funding and

other forms of support. Stakeholder theory (Hung 1998) assumes that organizations should be responsible to a range of groups in society other than just the owners of organizations. It is expected that organizations are more likely to respond to the broader social interests than the narrow interests of only one group. Therefore, different stakeholders are incorporated on boards, and boards play a political role to negotiate and resolve the potentially conflicting interests of different stakeholder groups in order to determine the objectives of the organization. In public health organizations, the principle of stakeholder involvement is less controversial, and the theory legitimates the boards because stakeholders represent society and users the organizations are serving.

In the governance of public health organizations, boards play a crucial role to ensure public accountability and good performance (Cornforth 2003). In general, there are two main functions of the boards: conformance and performance. Conformance refers to external accountability, which contains compliance with legal and regulatory requirements, accountability to shareholders or other stakeholders, supervision of management through oversight, monitoring performance, and ensuring adequate internal controls. In contrast, performance is about driving the organization forward to better achieve its mission and goals, which consists of policy formulation and strategic thinking (Garratt 1996).

Management of public health programmes

According to the WHO, public health programmes are managerial units with objectives, directors, managers, lines of command, budgets, and action plans, which are an integral part of health systems (Blas and Kurup 2010). Programmes targeting any of the determinants of health can be defined as health programmes. Health programmes not only focus on some aspect of the physical environments in which people live and work, but also address issues about people's behaviours, their biology, the social factors that affect them, or the health services they receive (Longest 2014). Public health programmes can range in scale, scope, and complexity, from local programmes in communities to global programmes, and the effective public health programmes need to be adapted to the local and broader contexts.

There are three different types of work in health programmes: direct work, support work, and management work. Management work involves

establishing the mission and objectives of a health programme and creating conditions for direct work and support work to accomplish that mission and fulfil the objectives. Programme management can be defined as 'the activities through which the mission and objectives of a programme are established and pursued by means of various processes using human and other resources' (Longest 2014). Programme management comprises planning, implementation, and evaluation, and specially, it contains two sets of activities: one is core activities, including developing/strategizing, designing, and leading; the other is facilitative activities, including decision-making, communicating, managing quality, marketing, and evaluating. Developing/strategizing means developing a new programme or improving services or products of ongoing programmes, which can result in programme adjustment decision and help the programmes adapt to continuously changing external environments (Ginter et al. 2013). Designing is to establish and change the intentional patterns of relationships among human and other resources within a programme, or the relationship of the programme to its external environment. Leading is the work of influencing other participants to contribute to the programme goals. Decision-making is simply making a choice between two or more alternatives, and continual decision-making is necessary due to the dynamic context. Communicating means that senders conveying ideas, intentions, and information to receivers, and the senders and receivers can be individuals, groups, or organizations. Managing quality is important to people who work in programmes or receive services, and there are six aims for quality improvement according to Institute of Medicine: safe, effective, patient centred, timely, efficient, and equitable (Institute of Medicine 2001). Marketing is a means bringing voluntary exchanges with people outside a programme to cross the boundary between a programme and its external environment. Evaluating is an essential programme activity to provide evidence of improving programmes (Longest 2014).

The environments of implementing public health programmes may change continuously, and implementation strategies need to be modified accordingly. Implementation science has been developed to ensure the implementation and external validity of programmes. In public health field, a widely used framework of implementation science is the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework (Gaglio et al. 2013). Reach is the proportion of individuals who

are willing to participate in public health programme. Effectiveness is the impact of public health programme on outcomes, including potential negative effects, quality of life, and economic outcomes. Adoption is the proportion of settings and intervention agents who are willing to initiate a programme. Implementation refers to the intervention agents' fidelity to the various elements of an intervention's protocol, which includes consistency of delivery as intended and the time and cost of the intervention. Maintenance is the extent to which a programme becomes institutionalized or part of the routine organizational practices. The implementation evaluation would help to improve the practice of public health programmes and promote them in a wider context.

Programme evaluation is an essential complement of public health programme management, and it gathers necessary information to improve and account for programme effectiveness. Evaluation needs to be integrated in routine programme practice, and involves all programme staff and stakeholders, not only evaluation experts. Center for Disease Control and Prevention of the US developed a Framework for Programme Evaluation in Public Health, to guide effective programme evaluation (Center for Disease Control and Prevention 1999). The framework is composed of six evaluation steps, and a set of 30 standards to assess the quality of evaluation activities. The six evaluation steps are to engage stakeholders, describe the programme, focus evaluation design, gather credible evidence, justify conclusions, and ensure use and share lessons. These steps are often completed in a cycle, and earlier steps provide the basis for subsequent progress. The first step is engaging stakeholders involved in or influenced by the programme. Stakeholders should be engaged, and their perspectives or concern are essential for programme implementation and outcomes. The second step is sufficiently describing the programme, which covers need, expected effects, activities, resources, stage, context, and logic model about the programme. The third step is focusing the evaluation design, and the evaluation must focus on the issues of greatest concern to stakeholders. The fourth step is gathering credible evidence, and indicators, sources, quality, quantity, and logistics are main aspects of evidence that can affect perceived credibility. The fifth step is justifying conclusions on the basis of evidence, which includes standards, analysis and synthesis, interpretation, judgement, and recommendations. The last step is ensuring use and sharing lessons learned, and translate lessons into informed decisions and appropriate actions. Five

elements are critical for ensuring use of an evaluation, which consist of design, preparation, feedback, follow-up, and dissemination. In addition, the second part of the framework is 30 standards to assess evaluation quality, and the 30 standards can be organized into four groups: utility, feasibility, propriety, and accuracy. Utility standards aim to satisfy evaluation users' needs, feasibility standards ensure the viability and practicability of the evaluation, propriety represents the ethics of the evaluation, and accuracy ensures the correctness of the evaluation findings (Lavinghouze and Snyder 2013).

Assessment framework of health governance

Major actors of health governance have increasingly paid attention to the assessment of health governance to ensure effective governance for better health outcomes (Barbazza and Tello 2014). Several institutions have developed principles of effective governance, and this section focuses on the five widely used frameworks of assessing health governance. They are the WHO's domains of stewardship (WHO 2000), the World Bank's six fundamental aspects of governance (Kaufmann et al. 1999), the UNDP's five governance principles (UNDP 1997), the WHO Eastern Mediterranean Regional Office's ten governance principles (Siddiqi et al. 2009), and the WHO Regional Office for Europe's TAPIC framework (Greer et al. 2016).

The WHO's domains of stewardship. The World Health Report 2000 identified four key functions which determine the performance and outcomes of health system—financing, resource generation, service delivery, and stewardship (WHO 2000). Stewardship focuses on the governments' role to take responsibility for guiding health system and improving population health. The objects of stewardship involve actors in provision and financing; the performance of stewards themselves; users and consumers, and non-health systems that affect health. WHO proposed six domains of stewardship: 'generation of intelligence, formulating strategic policy direction, ensuring tools for implementation, building partnership, ensuring a fit between policy objectives and organization structure and culture, and ensuring accountability' (WHO 2000). As a concretely applicable function for health system strengthening, stewardship, or responsibility of health sectors has been specifically allocated by legislation and law. However, there remain some gaps which call for ongoing collaboration among relevant

sectors, such as political and power dynamics, effective incentives for stewardship, good governance agenda and reform, as well as domestic resource mobilization (Brinkerhoff et al. 2019).

The World Bank's six fundamental aspects of governance. The World Bank measured six fundamental aspects of governance by subjective perceptions (Kaufmann et al. 1999). It defined governance broadly as 'the traditions and institutions by which authority in a country is exercised'. This includes '(1) the process by which governments are selected, monitored and replaced; (2) the capacity of the government to effectively formulate and implement sound policies; and (3) the respect of citizens and the state for the institutions that govern economic and social interactions among them' (Kaufmann et al. 1999). They are assessed from six basic governance aspects: voice and accountability, political instability and violence, government effectiveness, regulatory burden, rule of law, and graft. 'Voice and accountability' measures political process, civil participation, and political rights, and 'political instability and violence' refers to the possibility that the current government could be overthrown by unconstitutional and/or violent movements. 'Government effectiveness' focuses on the prerequisites for producing and implementing good policies, and 'regulatory burden' considers more about the policies themselves. 'Rule of law' refers to the rules of society being trusted and abided by agents, and 'graft' measures a straightforward focus of corruption. The cross-county comparison study provided a strong causal relationship from better governance to better development outcomes.

The UNDP's five governance principles. The UNDP defined governance as the exercise of political, economic, and administrative authority in the management of a country's affairs at all levels (UNDP 1997). The UNDP identified five principles for effective governance. The first principle is 'legitimacy and voice' through participation and consensus orientation to emphasize the voice of all individuals in decision-making and agreement based on the best interest. The second principle is 'direction' through strategic vision of leaders and the public, which is grounded on long-term perspective and understanding the complex historical and cultural context. The principle 'performance' refers to responsiveness along with effectiveness and efficiency, and 'accountability' incorporates accountability of policymakers, private sectors, and civil organizations with transparency built on free and direct information access. The last principle 'fairness'

means equity and inclusiveness together with rule of law to be fair and enforced equally.

The WHO Eastern Mediterranean Regional Office's ten governance principles. The WHO Eastern Mediterranean Regional Office developed an assessment framework as a gateway for effective governance of health systems by incorporating the three aforementioned frameworks (Siddiqi et al. 2009). They adapted the UNDP governance principles, and incorporated health-specific aspects of governance. Finally, they proposed ten governance principles for assessing health governance: strategic vision, participation and consensus orientation, rule of law, transparency, responsiveness, equity and inclusiveness, effectiveness and efficiency, accountability, intelligence and information, and ethics. Specifically, they summarized intelligence as an independent principle because of the unique nature of information asymmetry in health, which requires more intelligence to assess its creation, flow, and use. The ten principles have been disaggregated into 63 broad questions which relate to context, description, process, and outcomes of governance. The assessment framework has been applied in many low- and middle-income countries.

The WHO Regional Office for Europe's TAPIC framework. The WHO Regional Office for Europe proposed a robust framework with five key aspects of governance named TAPIC in 2016 (Greer et al. 2016). The TAPIC framework includes the five mutually exclusive elements of governance—transparency, accountability, participation, integrity, and capacity—which are inducted from a variety of literature. None of these elements are essentially a good thing, for they can be excessive or wrongly implemented. For each element, it can relate to a series of different policy and administrative tools, and be properties of both systems and individual organizations. The five elements are also mutually reinforcing on a broader scale. Improvement of one attribute could link to the development of other aspects as a result. This framework highlights the effectiveness of networks, the complexity of accountability, and the difficulty of distinguishing among different types of governance. But even if policies made in the name of transparency, accountability or participation does not guarantee the effectiveness or productivity, and in some cases can conflict with other attributes such as flexibility or capacity.

The five governance elements of TAPIC framework are introduced as follows. First, transparency means that institutions inform the public and

other actors of both upcoming decisions and decisions that have been made, and of the process by and the rationale on which decisions are being made. Transparency mechanisms include ‘watch dog committees, inspectorates, regular reporting, performance assessment and reporting, Freedom of Information legislation, and clear and useful public information’ (Greer et al. 2016). Second, accountability means that one actor must inform and explain the others of decisions, and can be mandated or sanctioned. The mechanisms of accountability include ‘contracts, other financial mechanisms such as pay for performance, laws that specify objectives, reporting and mechanisms, organizational separation, competitive bidding, conflict of interest policies, standards, codes of conduct, regulation, delegated regulation, standards, codes of conduct, and choice mechanisms that create horizontal accountability by letting marginal users vote with their fees’. Third, participation means that relevant parties acquire a meaningful stake and power in the process of decision-making in the institution. Participation mechanisms include ‘stakeholder forums, elections, consultations, appointed representatives, choice mechanisms, legal remedies, advisory committees, surveys, partnerships, joint budgets, joint workforce, etc., and more radically democratic innovations, such as participatory budgeting’. Fourth, integrity means that procedure of representation, decision-making and implement should be clearly specified, and roles and responsibilities should be clearly allocated. Integrity mechanisms include ‘solid and well-rewarded internal career trajectories, internal audit and censor, personnel policies, legislative mandate, budget, audit, procedures (e.g. document management, board behaviour, minuting meetings), and organizational roles and purposes’. Fifth, capacity refers to the ability to propose the policy which is fitting to resources in pursuit of goals. Mechanisms to improve policy capacity include ‘intelligence on performance, intelligence on process, research/analysis capacity, staff training, to improve their technical policy capacity, hiring procedures, to improve the quality of the policy bureaucracy, procedures to incorporate specialist advice into policy formulation and recommendations, and good purchase/make decisions’ (Greer et al. 2016).

Overall, effective health governance is a hybrid of principles and a dynamic process beyond specific policies, sector, and actors. The application of assessment frameworks of health governance requires the comprehensive understanding of the governance concept and the changing context around it.

Cases for health governance

Case for supranational health governance

Ebola epidemic in West Africa epitomes global health governance. Due to high population mobility across borders and international travel, this epidemic smouldered from sporadic rural areas to densely populated urban areas, from Guinea into Liberia, Siera Leone, and Nigeria. Ebola epidemic varied from previous local outbreaks in Africa, and led to bilateral or multilateral cooperation, instruction, coordination, and regulation (WHO 2015). Many types of actors responded to this epidemic together, including UN systems (WHO, the UN, and UNICEF), international CSOs, foreign governments, local governments, and communities, etc. (Table 6.8.4).

Table 6.8.4 Actors and their functions of governance in the Ebola epidemic of West Africa

Actors		Functions of governance
UN systems	WHO	Leadership and coordination, technique/laboratory/expert support, 'Roadmap' construction, case tracing, epidemic report, surveillance system building etc.
	UN	Health mission construction, priority airline support
	UNICEF	Early isolation and safe burial promotion, primary health construction
	US, UK, etc.	Surveillance system construction, treatment centre construction, worldwide epidemic prevention
International civil society organizations	Médecins Sans Frontières	Clinical support, psychological support, case tracing
	World Food Programme	Food, nutrition, and logistics support
	InterAction	Overall complement functions: health centres construction, clinical/psychological support, safety body disposal, etc.
Foreign governments Local governments	Ministry of Health, etc.	Case tracing, clinical services, epidemic investigation, and response
Community	Religious leaders, etc.	Health promotion

UN systems

As the most significant coordinator and supervisor, WHO with other partners engaged in case detection and management, and contact tracing from the very beginning. WHO prepared for case diagnosis by mobilizing its collaboration laboratories. Besides experimental support, WHO sent several multidisciplinary teams, which are specialised in epidemiology, laboratory services, risk communication, and social mobilization, to work with local staffs and community leaders. Meanwhile, WHO publicized the number of mortality and morbidity, and conveyed related concerns and advocations at

diverse meetings and assemblies, keeping the rest of the world aware of the latest epidemic situation. Furthermore, with the WHO leadership and more extricate and integrated partnership (local governments, partners, Ebola survivors, representative of airline and mining companies, and financial donors etc.), key priorities were identified to ensure the primary objectives and imperative moves for diverse partnerships. In addition to technical guidance and material support, WHO also urged governments to take actions on national laws and policy to control the outbreaks. An emergency committee was also organized to assess the Ebola situation under the provisions in the International Health Regulations with a declaration to further arouse international alert to the potential international spread. By launching 'Roadmap' for response to the epidemic, many actors (including US/UK government, UN Security council and NGOs) were coordinated and focused on the most urgent needs. WHO supported the three most affected countries to rebuild their disease surveillance and health service systems after 2014.

In 2014, UN declared its first-ever emergency health mission called UN Mission for Ebola Emergency Response (UNMEER) (UN 2015) as a temporary measure to meet immediate needs of the fight against Ebola. As a supplement of WHO, the UNMEER managers remain in the countries under the oversight of WHO and with the support of UN Resident Coordinators and UN country teams, quickly founding an air bridge to facilitate the flow of staff and materials and devising response plans based on 'Roadmap'. UNICEF devised Humanitarian Action for Children (HAC) framework to reduce transmission of Ebola and strengthen primary healthcare system (UNICEF 2016).

International civil society organizations

Under the WHO's leadership, international CSOs play various and harmonious roles in fighting against Ebola epidemic. Ahead of WHO, Médecins Sans Frontières (MSF) was one of the first international organizations involved in the Ebola outbreaks. Cooperating with WHO, MSF mainly provided services such as psychological support, health promotion, surveillance, and contact tracing. And MSF admitted over 10,000 patients to its Ebola management centres (MSF 2017). IFRC Red Cross teams worked with community elders and religious leaders to publicize fundamental Ebola knowledge by a range of communication channels, which

are useful for curbing unhygienic conventions and achieving early treatment. The World Food Programme (WFP) also provided food, nutrition, transport, and logistics support to people harshly attacked by the outbreak (WFP 2017). Nearly all of the organizations released the efficacy assessment of their responses during Ebola epidemic to ensure transparency and future improvement.

More than 60 NGOs engaged in the responses to the West Africa Ebola outbreak (UN 2014). Aligning with UN systems, NGOs made up for the shortage of health services handled by local governments. Meanwhile, NGOs complimented the role of the UN and other actors to evolve itself into a global coordination structure. In addition to running treatment units and tracing cases, NGOs were also involved in proper burial procedures and outreach programmes. Conducting more than 400 projects in the affected countries, NGOs served as a crucial echo chamber with clear objectives based on joint goals.

Foreign governments

The US and UK governments spared efforts to control Ebola epidemic. In Liberia, US Centre for Disease Control and Prevention, WHO and other partners assisted the MOH at locals to construct a national incident management system to improve coordination of response efforts (Marston et al. 2017). In Sierra Leone, civilian and military personnel and resources from UK bolstered the coordination of national and local responses to Ebola outbreak. These actions also strengthened these countries' future surveillance abilities, and built treatment centres in Liberia and Sierra Leone. Other countries, like China, addressed public health emergencies of international concerns through multilateral channels to keep epidemic from spreading into other parts of the world, and expanded their engagement to cooperation with international actors around the world (Huang 2017).

Local governments and community engagement

West African countries without previous experience of Ebola outbreak, were poorly prepared for this unexpected disease. However, their relatively rapid actions, timely reports, and cooperation with international aid teams prohibited the epidemic to some extent. The head of the Meliandou health post first informed district health officials when five fatal cases were

happening. With the partnership of experts from MSF and WHO, the pathogen has been finally narrowed down to Zaire species, the most lethal virus in the Ebola family within the first 6 months. As the main force of aid teams, local health officials accepted trainings offered by international organizations and NGOs, and assisted international experts to trace cases, treat patients, and disease surveillance, etc. Additionally, local community and religious leaders worked with experts to stress the hazard of high-risk cultural practices and traditional beliefs to promote scientific preventive measures in the general population.

Case for national health governance

Country/region-level health governance is also one significant dimension of governance. When it comes to public health within one country, the country's national strength usually dominates its roles and interactions among various actors. Here, two countries, the US and Ukraine, are taken as cases to illustrate the potential interactions and tools used to conduct national health governance.

Faced with diverse health threats, the US has already constructed ample cooperation and collaboration, involving governments at all levels, NGOs, communities, and even individual residents. Dominated by Health Departments, the public health system, community partners, and workforce all devote material and intelligence to improve national operational capacity, impacting every community programme and public health activity and further leading to better health outcomes, disparity reduction and better preparedness (Center for Disease Control and Prevention 2013). The federal government plays a crucial role in providing leadership (technique supports and formulation of public health goals, etc.), contributing operational and financial resources, financing research and higher education. State Governments and Local Health Departments further specify their duties as laboratory services, disease surveillance, community health assessment and assurance. Meanwhile, other organizations and institutes also serve as indispensable coordinating and complementary roles regarding public health, which includes NGOs, community coalitions, churches, schools, media, community services, business, and so on. Under such circumstance, the government is dominantly in charge of its national health affairs with the assistance of other parts of the society.

However, for countries without strong economic support, they are still able to achieve effective public health governance with systematic governance tools. The Ukrainian Swiss Perinatal Health Programme exemplifies how to balance interests of multisector stakeholders to promote sustainable development of a public health programme (Bodiang 2005).

During the Soviet era, disease prevention in Ukraine followed a centrally designed top-down strategy, which means that most preventive duties were delegated to residents, weighing much more on service's quantity rather than quality. After the Soviet Union collapsed, Ukraine went through a comprehensive reform transition, which also presented in the healthcare system. Meanwhile, Ukraine faced a negative population growth due to relatively high infant mortality rates, reduced life expectancy, health-related behaviour, and HIV epidemic. Stressed by its internal economic depressions and harsh health situation, the Ukrainian Swiss Perinatal Health Programme under the Ukrainian Ministry of Health (MOH), funded by the Swiss Agency for Development and Cooperation (SDC) and with technical assistance from the Swiss Centre for International Health (SCIH) of the Swiss Tropical Institute introduced a special pillar of health promotion in the realm of perinatal health of four of oblasts (Donetsk, Volyn, Ivano Frankyvsk, and Rivne).

At the very beginning, there was neither public fund nor civil engagement in decision-making in Ukraine, due to its previous absolute centrality governance. According to principles addressed in the Ottawa Charter of Health Promotion, approaches should be based on partnership creation and multiple communication strategies. However, due to disagreements between the two main parties (Ukrainian and Swiss), lengthy negotiations were taken. Finally on the basis of long-lasting trust, the MOH agreed to enlarge the range of health promotion actors and to promote a transparent tendering process based on its leadership and supervision position. With bilateral compromises, multisectoral collaborations between governmental and non-governmental actors at decentralized levels were constructed and programmes were handed over to local qualified NGOs, strengthening the local ownership for the modern approach to health promotion. With the foundation of both organization and techniques, local oblast government secured a funding commitment for future sustainable programmes without participants from Swiss.

To ensure the transparency and validity of these programmes, several workshops were launched to define local leading NGOs, topics of each oblast and the procedure of selection criteria. Training workshops were also held and contracts were signed to clarify accountabilities. Evaluations were processed through baseline analysis in order for further adjustments and improvements. With final evaluation workshops, further independent health promotion programmes under the charge of Ukrainian organization were guaranteed. Gains from these programmes laid foundations for future public health programmes.

Case for public–private partnership in public health

Quoting Reich as saying that ‘A public–private partnership (PPP) includes three points. First, the partnership involves at least one private for-profit organisation with at least one not-for-profit organisation. Second, the core partners provide a joint sharing of efforts and of benefits. Finally, partnerships in public health are committed to the creation of social value (improved health), especially for disadvantaged population’ (Reich 2000). PPPs have sprung up based on the global trend of health issues, especially those disturbing low- and middle-income countries. Both non-profit and for-profit organizations figured out their limitations that both of them were incapable of tackling with global health problems on their own.

Addressing the demand of products for combating disease associated with poverty, product development (PD) PPPs were flourished (Widdus and White 2004). The first PD PPP is International AIDS Vaccine Initiative (IAVI) for vaccine development, and Rockefeller Foundation sponsored the first several meetings, which laid the foundation of IAVI. The first drug development PD PPP is Medicines for Malaria Venture (MMV). With the first two organizations founded, Rockefeller Foundation and Bill & Melinda Gates Foundation have played as the major investors in promoting a number of product development ventures.

For PD PPPs, it is pivotal to manage effectively with other companies and institutions. Not like traditional pharmaceutical tycoons, which primarily maintain internal connections in product development, PD PPPs are usually small and implement their work though multilevel cooperation, thus management of interfaces with other actors are greatly significant to PD PPPs’ strategy.

Disease-endemic countries could help build ownership of potential products and also are served as integral components of the products development process, providing the end-user perspective, clinical trial capacity, and assessment. Effective clinical trials require physical sites, ethical review capacity, and the appropriate regulatory bodies to support trials and approve the products for use. Therefore, PD PPPs need to work closely with developing countries without losing their own focus and take measures to raise attention from international organizations like WHO to work together with local governments.

PD PPPs also need to work with other public sectors to ensure the availability of financing, public policy, and infrastructure once the product has been successfully invented. For example, if there are no existing regulatory bodies with sufficient capacity, it will definitely hinder the product's entry into usage. In addition, PD PPPs could also promote product-directed researches in academic institutions by investing related studies, for basic research community is the source of novel drugs, which is critical in product pipeline.

Additionally, private sector, both a source of candidate products and access to technical expertise, is increasingly important actors interacted with PD PPPs. Innovative licensing agreements with private sector is seen as one promising area of opportunity. This method is suitable for situation that the products of the company have both commercial and public health market. In this way, PD PPPs benefit from licensing high-potential products with technical support, while reserving the commercial gaining for the private company. One agreement between International Partnership for Microbicides and Tibotec (affiliated with the Johnson & Johnson companies) is just an example.

Conclusions

Governance is central to improve the health systems performance and achieve UHC. Good governance can enable the effective use of health finances, workforce, medicines, and information to deliver better health services and outcomes. Theories of principal-agent and network governance are introduced to better understand health governance at system level. In health governance system, the government, private sector, and civil society are the governing triangle (actors) to collectively pursue health goals, which

forms a whole-of-society governance approach for health. Each governing actor has its structures, roles in governance, governing tools, and mechanisms for interactions within and between the actors. They play health governance functions at four levels: supranational health governance, national health governance, governance of public health organizations, and management of public health programmes. At each level, tools to govern are central to carry out the health governance function and enable relationships among actors. Tools of governance can be classified into nine governance dimensions: accountability, regulation, participation, and consensus in decision-making, formulating policy/strategic direction, organizational adequacy/system design, generating information/intelligence, partnerships for coordination and collaboration, engagement of community, communication, and transparency. Five assessment frameworks for health governance are further introduced to help achieving effective governance. And several cases of health governance are introduced for better understanding.

Implementation science and translational public health

Wafaa M. El-Sadr, Judith Wasserheit, Bryan Wiener, Andrea Howard, Catherine Hankins, Patricia J. Culligan, and Katherine Harripersaud

Introduction

The pace and scope of innovation to improve health and the potential to increase health equity have never been greater. Yet translation, implementation, and scale-up of efficacious biomedical, behavioural, and socio-structural interventions into policies and their adoption into standards of care, or large-scale programmes has remained slow and uneven. In the United States, on average, it takes almost a generation—17 years—to transform less than 15% of original research into practices, programmes, or policies that improve patient care and population health (Balas and Boren 2000). In many low- and middle-income countries (LMICs), closing this 'know-do gap' or the 'knowledge to action gap' may take far longer, although in exceptional cases 'leapfrogging' has been noted with rapid adoption of innovation. Furthermore, interventions that prove efficacious in randomized trials may not be effective when introduced at large scale under 'real world' conditions without appropriate adaptation, or stakeholder and government buy-in, particularly in fragile, overburdened health systems or new social, political, or demographic contexts (Chen et al. 2004).

Implementation science health-related research is a rapidly emerging paradigm that addresses the urgent need to close the 'know-do gap' by providing new conceptual frameworks and tools to evaluate the factors that could influence the successful closure of this gap. Implementation Science uses rigorous methods from multiple disciplines and sectors to inform how best to implement and scale up evidence-based interventions, or intervention packages, in order to improve population health. Implementation science expands the opportunities and responsibilities of

health researchers beyond the laboratory, bench, clinic, and bedside, by asking them to also focus on how health system, health facility, community, national, and transnational contexts impact on closing this gap (Elzarrad et al. 2013). The primary focus of implementation science has evolved differently in the United States (US) in contrast to the global health context. With growing support from the US National Institutes of Health (NIH) during the past 15 years, implementation science in the health sciences blossomed with a central focus on the translation of biomedical advances into widespread clinical practice, often working with providers and patients at health facility level (Zerhouni 2003; Glasgow et al. 2012; Neta et al. 2015). Over the same period, the primary implementation science focus globally was on translating a broad array of biomedical, behavioural, information technology and policy interventions into large-scale programmes in resource-limited settings, frequently working with policymakers and programme managers at the national or transnational level. This approach to implementation science was shaped by support from multilateral and bilateral organizations such as the World Health Organization (WHO), the Joint United Nations Program on HIV/AIDS (UNAIDS), the US President's Emergency Plan for AIDS Relief (PEPFAR), the United States Agency for International Development (USAID), the Centers for Disease Control and Prevention (CDC), the World Bank, The Global Fund for AIDS, Tuberculosis and Malaria (GFATM), and the US NIH Fogarty International Center among other NIH institutes (Madon et al. 2007; The Global Fund to Fight AIDS Tuberculosis and Malaria USAID World Health Organization 2008; Padian et al. 2011).

At the same time, implementation science, as a science, continues to evolve, so much so that even its boundaries are continually being demarcated. The following sections describe current thinking around defining implementation science, its governing frameworks and research designs, and the critical role of stakeholder engagement in applying implementation science.

Definitions of implementation science

In new, rapidly evolving fields, consensus on their primary focus, core methods, boundaries, and terminology often emerge over time, as a critical mass of thought leaders are galvanized, engaged, and confronted with new

challenges. This is the case for implementation science (Odeny et al. 2015). This is manifested in the diversity of definitions for implementation science which reflects both the relative youth of this field and the different factors that influence implementation of this emerging field in high-income countries and in LMICs. One early and widely cited definition from researchers based in the United Kingdom and the US frames implementation science as 'the scientific study of methods to promote the systematic uptake of clinical research findings and other evidence-based practices into routine practice, and hence to improve the quality and effectiveness of health services' (Eccles 2006; Eccles et al. 2009). Others have offered broader definitions that go beyond a clinical, facility-based focus on quality improvement to call for 'applied research that aims to develop the critical evidence base that informs the effective, sustained and embedded adoption of interventions by health systems and communities' (Allotey et al. 2008) Some characterize implementation science even more broadly as the study of the determinants and processes that influence successful integration of evidence-based innovations in specific settings, and the results of implementation and scale-up, as well as related issues such as the degree of fidelity with which core components are translated and other components are adapted as these innovations are introduced and taken to large scale (Hirschhorn et al. 2007; Rabin et al. 2008; Peters et al. 2013; Peters and Adam 2013; National Implementation Research Network 2015). Common features of all of these definitions include the following: (1) applying rigorous, systematic research methods to guide the introduction, improvement or expanded use of interventions for which there is strong evidence of efficacy from earlier phase research; (2) a multidisciplinary or transdisciplinary approach; and 3) collaboration between researchers and relevant stakeholders, prominently including programme implementers and policymakers throughout the process (Sanders and Haines 2006; Bhattacharyya et al. 2009; Knapp and Anaya 2013; Bauer et al. 2015).

To accelerate improvements in global health and progress towards national or transnational goals such as the Sustainable Development Goals (SDGs), the authors of this chapter support the following broad definition, i.e. that *Implementation science is a systematic, scientific approach to ask and answer questions about how we get 'what works' to people who need it with greater speed, fidelity, efficiency, quality, sustainability and coverage.*

This definition promotes the application of at least 10 research approaches utilized by different disciplines as essential for understanding and improving the determinants, processes, and outcomes of implementation and, ultimately, scale-up and sustainability to achieve population-level health benefits (Kemp et al. 2018). These research approaches include impact evaluation, economic evaluation, qualitative health systems research, operations research, systems analysis and improvement, organizational assessment, stakeholder and policy analysis, dissemination research, social marketing, and surveillance and data systems. Although these 10 research methods are not exhaustive, together they provide a core set of tools to assess and iteratively improve implementation and scale-up of health interventions. These methods enable exploration of a synergistic continuum of three categories of outcomes for implementation science from most proximal such as acceptability, appropriateness, feasibility, cost, adoption, fidelity, penetration, scale-up, and sustainability; through intermediate *service delivery outcomes* such as efficiency, equity, timeliness, and patient-centredness; to distal *health outcomes*. While improvements in service delivery and health outcomes are the ultimate criteria for evaluating the effectiveness of implementation strategies, implementation outcomes may be early signals of successful implementation, and preconditions for achieving service delivery and health objectives.

The boundaries of the terminology of implementation science also remain to be defined, as are the boundaries of other closely related, emerging fields, such as improvement science, programme science, and delivery science, potentially creating confusion in terminology—with each aiming to improve health despite having slightly varying primary foci and approaches. For example, improvement science is primarily concerned with quality improvement, one of the 10 core implementation science methods (Foundation 2011). Programme science flips the standard paradigm of ‘getting research into practice’ and focuses on ‘getting research out of practice’ by working with programme staff to develop research questions and conduct research (Blanchard and Aral 2011). Delivery science prioritizes strengthening the capacity of health systems using intersectoral public policy and financing approaches to improve health and development outcomes (Kim 2018). Finally, the science of scale-up prioritizes policy and implementation research that focuses on the scaling of existing health tools

and delivery services (Kruk et al. 2016). As these fields mature, realignments or mergers may occur, leveraging the complementary strengths and learnings.

Implementation science frameworks

Implementation science offers several frameworks for guiding research and practice. In a 2012 review, Tabak et al identified 61 frameworks for supporting the implementation of evidence-based interventions (Tabak et al. 2012). Additional frameworks have been proposed since then. Selecting a framework can be challenging given the number of options available (Birken et al. 2017). Nilsen categorized implementation science frameworks into three types based on three common objectives for implementation science: (1) process models for describing or guiding the process of implementation; (2) determinants frameworks for identifying the factors that influence implementation; and (3) evaluation frameworks for assessing the degree of implementation success. Although specific frameworks can address more than one of these objectives, these general types of frameworks can help guide the selection of a framework for implementation research and practice (Nilsen 2015).

The first type of frameworks, process frameworks, specify the steps, stages, or phases of implementing evidence-based interventions. Process frameworks such as the Knowledge to Action (K2A) Framework (Wilson et al. 2011) and the Canadian Institutes of Health Research (CIHR) Model of Knowledge Translation (Canadian Institutes of Health Research) describe a sequence that begins with research on the effectiveness of interventions, then moves to the dissemination of those interventions to targeted audiences, and then moves to the implementation of those interventions in real-world settings. Other process frameworks, such as the Quality Implementation Framework (QIF) (Meyers et al. 2012), the Stetler Model (Stetler 2010), and the Ottawa Model (Logan 2010) offer practical advice for planning and carrying out an implementation effort. These frameworks are useful for guiding implementation because they not only highlight the key tasks that should be performed, but also prescribe the order in which they should be performed. The QIF, for example, delineates four phases of implementation: initial considerations regarding the host setting (Phase One), creating a structure for implementation (Phase Two), ongoing

structure once implementation begins (Phase Three), and improving future applications (Phase Four). The QIF further identifies 14 critical steps across these four phases that are believed to result in high-quality implementation. Although process models describe, or in some cases prescribe, a logical sequence of steps and depict an idealized view of the implementation process, actual implementation is often nonlinear and disordered.

Unlike process frameworks, which describe steps or stages of implementation, the second type of frameworks, determinants frameworks, identify factors that influence implementation, either positively in the case of facilitators or negatively in the case of barriers. Such frameworks are useful for assessing the context in which implementation occurs and, consequently, identifying strategies to overcome barriers or harness facilitators. They are also useful for explaining why implementation was successful or not in specific settings or why implementation success varied across multiple settings. The Consolidated Framework for Implementation Research (CFIR) is a commonly used determinants framework in implementation science, with growing use in global health (Damschroder et al. 2009). The CFIR synthesizes 19 implementation science frameworks by organizing 37 factors into five domains: intervention characteristics, outer setting, inner setting, individuals involved, and implementation processes. The attractiveness of the CFIR derives from its comprehensiveness, applicability, and flexibility; the CFIR's developers encourage users to 'select constructs from the CFIR that are most relevant for their particular study setting and use these constructs to guide diagnostic assessments of implementation context, evaluate implementation progress, and help explain findings in research studies or quality improvement initiatives' (Damschroder et al. 2009). The Theoretical Domains Framework (TDF) is another widely used determinants framework that, like the CFIR, synthesizes 33 psychological and behaviour change theories by organizing more than 100 constructs into 14 theoretical domains, such as knowledge, skills, intentions, goals, and social influences(Cane et al. 2012). While neither the CFIR nor the TDF hypothesizes causal relationships among determinants, both frameworks acknowledge that such relationships exist.

Thirdly, evaluation frameworks offer a conceptual structure and a set of metrics for gauging implementation success. The two best known evaluation frameworks in implementation science are the Implementation Outcomes Framework (IOF) (Proctor et al. 2011) and Reach, Effectiveness,

Adoption, Implementation, and Maintenance (RE-AIM) framework (Glasgow et al. 1999). The RE-AIM Framework is described here since the IOF was introduced earlier in this chapter. Developed for evaluating the public health impact of health promotion programmes, RE-AIM identifies five metrics that signal the applicability, scalability, potency, and sustainability of programmes or interventions in 'real world' settings (Glasgow et al. 1999). These metrics are as follows: the *reach* of the programme within the intended target population, the *effectiveness* of the programme, the *adoption* of the programme by target settings or staff, the *implementation* of the programme in terms of the consistency and quality of programme delivery, and the *maintenance* of programme delivery and programme effects. The RE-AIM Framework is particularly useful in global health because it balances classic concerns about programme effectiveness with considerations relevant to implementation and scale up, such as adoption among targeted staff, settings, or institutions and coverage (reach) within targeted populations.

Table 6.9.1 highlights the relative strengths and limitations of the three main types of implementation frameworks described by Nilsen. Two broad observations are noteworthy. First, the different types of frameworks have complementary strengths and limitations and, thus, work well together in implementation research or practice. For example, determinants frameworks such as the CFIR or the TDF can be employed in the pre-implementation stages of process models such as the QIF to assess needs and resources, fit of the evidence-based intervention and the setting, and capacity or readiness for implementation. Likewise, determinants frameworks and evaluation frameworks can supply the independent and dependent variables in research investigating the effects of context on implementation success or failure. Second, many, if not most, implementation science frameworks have been developed in high-income countries with Western cultures. Although frameworks like the CFIR have been used in implementation science in global health, adaptation is likely needed to improve their fit with and utility for studying implementation in LMICs and countries with non-Western cultures.

Table 6.9.1 Strengths and limitations of implementation science frameworks

Framework type	Strengths	Limitations
Process models (e.g. QIF, Ottawa model)	• Include actionable steps, useful outside research context • Prescribe a sequence for performing implementation tasks	• Describe a rational, ideal sequence rarely observed or practicable in implementation • Focus neither on determinants, nor outcomes
Determinants frameworks (e.g. CFIR, TDF)	• Include large number of potential determinants at multiple levels • Synthesize and harmonize prior frameworks, theories, and models • Include data collection and analysis tools • Useful for formative, concurrent, or summative evaluation	• Provide no guidance for implementation • Focus on determinants, not outcomes • Need adaptation for use in LMIC contexts and non-Western cultural contexts • Include fewer determinants at higher levels (e.g. community, policy) • Reliable, valid measures of many constructs lacking
Evaluation framework (e.g. IOF, RE-AIM)	• Include multiple outcomes for evaluating public health impact • Differentiate implementation outcomes from effectiveness • Specify how outcomes can be quantitatively assessed • Outcomes can be measured at multiple levels	• Provide no guidance for implementation • Focus on outcomes, not determinants • Reliable, valid measures for some outcomes lacking • Relations among some outcomes need clarification

Scale-up frameworks

Although implementation science frameworks could be used to design, guide, and evaluate scale-up efforts, Barker et al. identified 45 theories, frameworks, and models that have been developed specifically for scaling up evidence-based health interventions (Barker et al. 2016). Two well-known process frameworks for scale-up are the Management Systems International (MSI) Scaling Up Management Framework for Practitioners

and the ExpandNet/WHO Framework. The MSI Framework describes three main steps: developing a scale-up plan, establishing the preconditions for scaling up, and implementing the scale-up process. Within these steps, the framework offers guidance for performing 10 tasks: creating a vision, assessing scalability, filling information gaps, preparing a scaling-up plan, legitimizing change, building a constituency, realigning, and mobilizing resources, modifying and strengthening organizations, and coordinating action.

The ExpandNet/WHO Framework outlines a nine-step process for developing a scale-up strategy and offers practical advice for conducting each step. The ExpandNet/WHO Framework also could serve, as a determinants framework. It conceptualizes scale-up as a system of five inter-related elements: (1) the innovation that is being scaled up; (2) the resource team, or the individuals and institutions that seek to facilitate the innovation's wider use; (3) the user organization, meaning the institutions or organizations within which the innovations are expected to be widely adopted and implemented; (4) the scaling-up strategy, which designates the means by which the innovation is communicated, transferred, or otherwise promoted; and (5) the environment in which scaling up takes place. For each element, the Framework describes attributes of success, many of which correspond to the constructs found in the CFIR. For example, the attributes of success for the innovation include evidence strength and credibility, observability, relative advantage, compatibility, trialability, and complexity. The Framework's attributes of success can be viewed as determinants that hinder or facilitate scale-up. A distinctive feature of the Framework is its delineation of strategic choices regarding the type of scaling up used; the process of communicating the innovation and preparing users in its application; the organizational options selected in implementing the process; assessing costs and resource mobilization; and monitoring and researching the process and outcomes of scaling up. Like the ExpandNet/WHO Framework, Yamey's conceptual framework also identifies success factors (i.e. determinants) that fall into six categories representing different components of the scaling up process: attributes of the specific tool or service being scaled up, attributes of the implementers, the chosen delivery strategy, attributes of the 'adopting' community, the socio-political context, and the research context (Yamey 2011).

Although there are many approaches and methods for monitoring and evaluating scale-up, including impact evaluation, no evaluation framework has emerged in global health that offers a conceptual structure and general set of metrics for evaluating scale-up efforts. While the RE-AIM Framework was developed to evaluate the public health impact of health promotion programmes in the US context, it is suitable for use as an evaluation framework beyond the US because it balances traditional concerns about programme effectiveness with considerations relevant to scale up, such as programme coverage (reach) in a targeted population, programme spread (adoption) among settings and people expected to deliver the programme, consistency and quality of programme delivery (implementation), and programme integration (maintenance) into government policies and organizational practices.

Research designs

A wide variety of research designs have been employed in implementation science. In 2017, Brown et al. identified three broad categories of designs used in implementation science within the traditional translational research pipeline, including those that provide (1) within-site; (2) between-site; or (3) within- and between-site comparisons of implementation strategies, to determine how to make an effective clinical or preventive intervention work within community and/or service settings (Brown et al. 2017). As these designs focus on interventions that have already demonstrated effectiveness, the emphasis of such designs is on measuring (1) healthcare process, or activities undertaken by the health system, and (2) healthcare output, or observable measures of service delivery provided to the target population, as opposed to health outcomes or health-related behaviours of individuals who are the ultimate target of the intervention. Although many of these designs employ random assignment, and thus have high internal validity, some are observational or quasi-experimental, and are preferable in instances when randomization is not feasible or warranted, such as when policies are disseminated or implemented by law.

Within-site designs evaluate implementation successes or failures by studying changes that occur inside an organization, community, or system. The simplest design is a post design, which examines healthcare process and/or utilization after introduction of an implementation strategy aimed at

delivery of an evidence-based intervention in a novel health setting. On the other hand, in a pre-post design, the impact of a new implementation strategy for an existing intervention is inferred by comparing process and/or output measures prior to and following adoption of the strategy. A multiple-baseline times-series design is a variant of the pre-post design in which data are collected at multiple time points to examine whether the effects of the implementation strategy are sustained.

Between-site designs compare healthcare process and outputs among sites that have different exposures. In a new versus implementation-as-usual design, some sites are assigned to an innovative implementation strategy while others maintain the usual condition. Process and output measures for the two strategies are then compared over the same time period. When evaluating complex, multilevel implementation strategies, a cluster-randomized design is often employed, in which sites (health facilities, communities, or organizations) are randomly assigned to either the new implementation or usual-practice condition, and endpoints are assessed for all eligible individuals in both conditions. If the implementation strategy is designed to achieve impact at a smaller unit of the organization, then randomization can occur at the level of the ward, team, or provider within each site. Individual-level randomization can also be utilized, if the intervention is delivered at the patient or individual level.

A head-to-head randomized implementation trial design, also known as a comparative effectiveness implementation trial, tests which of two active implementation strategies is more successful in implementing an intervention, in terms of quality, quantity, or speed of intervention implementation. The same intervention is used for both study arms, and sites are randomly assigned to one of the implementation strategies. In a variant of this design, sites are randomized to one of two implementation strategies that focus on different patient populations of individuals or patients and target different outcomes. With this design, each site serves as both an active intervention and a control.

Factorial designs evaluate a combination of two or more implementation strategies simultaneously. Each experimental factor has two or more levels (e.g. presence or absence, or low, medium, or high intensity of implementation). With a 2 × 2 factorial design, units are randomly assigned to one of four conditions (i.e. strategy 1, strategy 2, strategy 1 and 2 combined, or neither strategy), and estimates of the effect of each factor by

itself and their interaction are derived. In an incomplete, or fractional, factorial design, one or more arms of a complete factorial are excluded. This design may be chosen if it is deemed unethical to withhold both implementation strategies from participating sites, or alternatively if it would be too difficult to implement both strategies at the same site.

A multiphase optimization strategy implementation trial (MOST) design enables consideration of a large number of components that comprise an implementation strategy, including those involving leadership, the clinic level, the provider level, and key processes such as planning, training, financing, restructuring, and quality management. Testing each combination of these components is often not feasible, the MOST design can be used to identify and test an optimal intervention. This design consists of three phases: preparation, optimization, and evaluation. In the preparation phase, components are selected and pilot tested using an explicit optimization criterion. In the optimization phase, a randomized trial is conducted to assess the effectiveness of these components, using a fractional factorial design. Based on the trial's results, the group of components that best meets the optimization criterion is identified. In the evaluation phase, a standard randomized implementation trial is conducted that compares the optimized implementation strategy with an appropriate comparison condition.

A sequential multiple assignment randomized implementation trial (SMART) design is an adaptive approach that involves multistage randomizations such that the site-level implementation process can be modified if unsuccessful. In the latter design, the adaptation probability within each site is constant. A variant of this design is the SMART design with adaptive randomization (SMART-AR), in which the randomization probability of each strategy is updated based on the outcomes in the other sites, so that the expected outcome is optimized.

A doubly randomized, two-level nested, or split-plot implementation design is used to assess whether experimental implementation factors directed towards two different hierarchical levels (e.g. provider and patient) have additive or synergistic effects.

Within- and between-site comparison designs are also known as rollout randomized implementation trial designs. In these designs, sites begin in one implementation condition and cross over to another, and the timing of the start of the new implementation strategy is randomly assigned. The simplest design is a stepped wedge, or dynamic wait-listed, design, in

which all sites start in the implementation-as-usual setting, and then cross over at randomly determined time intervals, until all are receiving the new implementation strategy. At each time interval, a between-site comparison of those sites assigned to the new implementation strategy and those remaining in the control condition is made. Additionally, a within-site comparison can be conducted when sites cross over from the usual practice setting to the new implementation strategy. In a head-to-head rollout trial, all sites start in the implementation-as-usual setting and then at a predetermined time, are randomly allocated to one of two new implementation strategies, which they continue until the end of the study.

Other research designs encompass elements beyond the traditional translational research pipeline, including hybrid designs, discrete choice experiments, and designs that involve simulation. Curran et al. described three effectiveness implementation hybrid design constructs, all of which focus a priori on assessing both implementation and clinical effectiveness (Curran et al. 2012). Type 1 hybrid designs primarily test the effects of a clinical intervention on health outcomes, while collecting information on its delivery and/or its potential for implementation in a real-world setting. The latter is usually achieved through a process evaluation that ascertains barriers and facilitators to delivering the intervention, as well as potential modifications to the intervention that could be made to maximize implementation. Type 2 hybrid designs simultaneously test a clinical intervention and an implementation strategy. Type 3 hybrid designs primarily test an implementation strategy, while observing or gathering information on the clinical intervention's impact on health outcomes.

Another research method is discrete choice experiment approach, a health economics tool that elicits preferences from decision makers over alternatives, with each alternative consisting of several attributes. It can be used pre-implementation to elicit information from a variety of stakeholder groups, including patients, caregivers, providers, and administrators, to assess the potential acceptability or appropriateness of health services, products, or implementation strategies, in order to improve implementation (Salloum et al. 2017).

Lastly, mixed methods designs that collect, analyse, and merge both quantitative and qualitative data are often utilized in implementation science. Typically, qualitative methods are used to identify strategies for facilitating implementation of an evidence-based intervention, or to obtain

an in-depth understanding of reasons for implementation success or failure, while quantitative measures are used to test a hypothesis and assess predictors of successful implementation (Palinkas et al. 2011).

In summary, choosing a research design for a specific context is a complex process that requires consideration of the research questions, existing knowledge base, stakeholder values, and available resources. Table 6.9.2 shows the relative strengths and limitations of various research designs.

Table 6.9.2 Strengths and limitations of research designs

	Strengths	Limitations
Within-site designs		
Post design of an implementation strategy to adopt an evidence-based intervention in a new setting	• Useful for assessing factors that predict programme adoption • Useful when new health guidelines or changes in policy occur	Lack of comparison group limits internal validity
Pre-post design of an implementation strategy of an intervention already in use	• Can be used to assess adoption of a guideline or policy by a healthcare system • Can examine whether an implementation strategy has sustained effects by collecting data at multiple time points	• Requires information about pre-implementation levels • Does not account for secular trends that may influence healthcare processes and outputs
Between-site designs		
New implementation strategy vs. usual practice implementation design	• Can determine whether new implementation strategy improves reach or utilization of a healthcare intervention, compared with standard of care • Use of a contemporaneous control condition and randomized assignment of the implementation conditions strengthens internal validity	• May be subject to assignment bias, if sites assigned to the new implementation strategy do not accept some of the strategy components • May be subject to contamination, particularly if randomization occurs at a lower level of the organization
Head-to-head randomized implementation trial design	• Can compare two implementation strategies • Use of contemporaneous comparison group and random assignment strengthens internal validity	Resource-intensive, as both implementation strategies must be executed with equivalent attention to fidelity

	Strengths	Limitations
Factorial designs for implementation	• Can assess whether there is an interaction between two implementation strategies • Use of contemporaneous comparison group and random assignment strengthens internal validity	Resource intensive Complex to design, implement, and evaluate
Multiphase optimization strategy implementation trial design (MOST)	• Enables consideration of a large number of implementation strategy components	Time and resource intensive Complex to design, implement, and evaluate
Sequential multiple assignment randomized implementation trial (SMART) implementation design	• Optimizes resource allocation, as additional strategies are only tested in sites that do not achieve desired outcomes	Time and resource intensive Complex to design, implement, and evaluate
Doubly randomized, two-level nested designs	• Can assess whether there is an interaction between two implementation factors directed towards two distinct hierarchical levels	Complex to design, implement, and evaluate
Within- and between-site comparison designs		
Stepped wedge design	• Can use when there are perceived advantages to a new implementation strategy, or it is unethical to withhold a new implementation strategy throughout the study	Not appropriate for all interventions Complex to design, implement, and evaluate

	Strengths	Limitations
Head-to-head rollout design	• Can compare two new implementation strategies against the standard of care	If no randomization, does not obviate risk of bias
Effectiveness implementation hybrid designs		
Hybrid type 1	• Implementation data can inform subsequent implementation research trials	Require additional research expertise and funding
Hybrid type 2	• Can facilitate more rapid translation of research findings into routine practice	Require additional research expertise and funding • Some design compromises will likely be necessary in one or both aims given funding limits
Hybrid type 3	• Useful if suspected that clinical intervention effects susceptible to change during implementation in new settings or under less controlled conditions	Primary data collection on patient outcomes may not be feasible with large multisite implementation study, thus may need to rely on subsample of patients, medical record review, and/or administrative data
Discrete choice experiment		
	• Provides stepwise method for selecting and tailoring an implementation strategy to a particular context • Guides stakeholders to consider multiple attributes of an implementation strategy, which enhances the precision with which strategies are tailored to a specific setting	Primary data may be necessary to establish attributes and attribute levels, particularly in low-income settings

Stakeholder and community engagement

The seeds for effective implementation science, whether it takes the form of a phase four trial, a population-level study, or other design, are sown during the conduct of the research that strengthened the scientific evidence propelling forward a line of investigation. In particular, whether effective stakeholder engagement was accomplished in the preceding trials or other research which could have a direct effect on the feasibility of conducting follow-on studies at the end of a clinical trial or other such studies.

Transparent, mutually beneficial, respectful, sustained relationships between research funders, sponsors, researchers, implementers, community members, and other stakeholders are critical to the success of any study. These relationships set the stage for effective collaboration and shared ownership of all aspects of the research process, starting at problem formulation and in the research design stage. In the context of implementation science research, they can directly influence the relevance of the research; the likelihood that interpretable, valid data and reliable results will be produced; and the eventual uptake of study outcomes.

The foundational principles underpinning effective stakeholder involvement, as now defined in Good Participatory Practice (GPP) guidance in several research fields, drew inspiration from the controversies and debates that arose in 2004 regarding pre-exposure prophylaxis (PrEP) trials for HIV prevention where national political leaders in Cambodia and Cameroon opposed these trials (Mills et al. 2005; Singh and Mills 2005; Global Campaign for Microbicides 2009a; Global Campaign for Microbicides 2009b). In response, the Joint United Nations Programme on HIV/AIDS (UNAIDS) convened the *Creating Effective Partnerships in Research* process in 2005 (UNAIDS 2006) that resulted in a strong recommendation for the development of research guidelines for community stakeholder engagement.

Following a series of regional consultations that defined the key elements needed for creating effective partnerships for biomedical HIV prevention trials, these were published as the GPP-HIV guidelines in 2007 (UNAIDS and AVAC 2007). GPP was first cited in the methodology of a scientific publication of trial results in 2010 (Grant et al. 2010). A revised edition of the GPP-HIV guidelines (UNAIDS and AVAC 2011) followed GPP application in different settings and formal consultations with stakeholder groups in Africa, the Americas, Asia, and Europe. Subsequently, the GPP guidelines were adapted for tuberculosis drug trials in 2012 (Critical Path to

TB Drug Regimens 2012) and the WHO published GPP guidelines in 2016 for trials of emerging (and re-emerging) pathogens that are likely to cause major outbreaks in the future and for which few or no interventions exist (WHO 2016). Web-based training curricula, tools, application examples, and other materials are currently available to assist stakeholders to understand, implement, and monitor GPP (AVAC 2018). Further, a Centre of Excellence is under development (Coalition to Accelerate and Support Prevention Research 2017) with an implementation framework that further advances GPP practitioners' understanding, ability, and technical skills to carry out GPP effectively.

Determining who the relevant stakeholders are for specific implementation research study is an essential step. Broadly, stakeholders are all individuals or groups of individuals who can influence or are affected by the conduct or outcome of the research, i.e. all those who have a stake. They include national research organizations and scientific councils, Schools of Medicine and Nursing, and ministries of Health, Education, Science, and Justice as well as others that may be involved in the eventual implementation of the interventions. Importantly, an important stakeholder group is the population to be recruited, study participants, families of study participants, people resident in the area where the research is to be conducted, local support groups or networks, religious leaders, opinion leaders, media, local healthcare authorities, healthcare providers, traditional healers, private sector partners, non-governmental organizations (NGOs), and community-based organizations (CBOs) including women and youth groups.

Local contextual analysis may be needed to define such stakeholders, the optimal level of engagement needed, and the types of structures to be created to facilitate stakeholder engagement. Funding for such contextual analyses should be anticipated, with time frames determined in part by the urgency of the issue to be evaluated. Formative research, qualitative studies, geospatial mapping, key informant interviews, and other methodologies assist in defining relevant stakeholders, including community, for implementation research. In a health emergency, the formative research phase should be nimble and rapid, aiming at stakeholder engagement to identify key voices to participate from the outset in discussions of trial design (Holzer et al. 2014). In less urgent situations, communities can be engaged, for example, in the randomization process itself, as was done in

the HPTN071 (PopART) Study, a cluster-randomized trial conducted in South Africa and Zambia (Bond et al. 2016).

It should be noted that stakeholders may have competing interests and perspectives. Disagreements during implementation research may arise from power imbalances, differences in social organization, hierarchies, gender issues, relative socioeconomic disparities, and other factors. A stakeholder engagement plan, developed together by research teams and relevant stakeholders, can define the range of stakeholders to be engaged; detail the frequency and types of engagement methods to be used, such as public meetings, workshops, joint decision-making models, or delegated decision-making; and clarify the type of engagement appropriate for each stakeholder, such as being informed, consulted, collaborated with, or emancipated to make decisions (Ray and Miller 2017). Such a plan can also delineate the nature of support for initial and ongoing activities aimed at building stakeholder capacity to understand concepts, purposes, practices, and limitations of implementation research so that the ability of stakeholders to provide meaningful input to the research process will be enhanced. Importantly, it clearly describes the methods to be used for resolution of differences and lays out key principles that underpin partnerships among stakeholders, including respect, fairness, integrity, transparency, accountability, and autonomy (UNAIDS and AVAC 2011).

Effective stakeholder and community engagement in implementation research is not only an ethical imperative, it enhances the conduct of research, contributes to robust research outcomes, and creates both impetus and support for scale-up following proven results.

Future directions

Implementation science is an important research approach that offers the potential to bring to practice many of the discoveries that exist in scientific journals. Its focus on advancing the learning of implementation and of scale-up is directly linked to the collective ability to advance the health and well-being of populations around the world. Yet, much remains to be done to achieve broad knowledge of this approach among researchers, funders, and policymakers. The diversity of frameworks and methods put forth for implementation science also highlights the need for a maturation of the field and for consensus building among experts in implementation science.

Additionally, efforts are needed to overcome some of the myths that relate to this research approach including highlighting its importance and the rigorous manner in which implementation research can be designed and conducted.

Creating a new generation of researchers who are knowledgeable of implementation science requires an investment in specific education and training opportunities for young scholars, as well as investigators at various career stages. These training programmes should emphasize a multidisciplinary approach including how to synthesize information across disciplines, test and adjust approaches in collaboration with stakeholders, use data to inform policies, and ways to formulate scalable interventions (Means et al. 2016). Such training would allow for broad health systems perspective and understanding of multisectoral ancillary effects of health interventions and policies. Core competencies for these programmes continue to be refined and need to be foundational and responsive to advances in the field (Gonzales et al. 2012; Chambers et al. 2017). Mentorship is also a critical component of advancing this science and should accompany and supplement any formal training programmes. An evaluation of a 2-year mentorship programme focused on dissemination and implementation research for cancer prevention and control resulted in improved dissemination and implementation research competency, high satisfaction for emotional support, career planning, and sharing resources (Padek et al. 2018).

With the adoption of implementation science as a means to help translate evidence-based-interventions related to health into positive outcomes for patients and communities, other fields have also turned to this approach as relevant for closing the know-do gap. Examples include initiatives related to special education (Cook and Odom 2013), conservation biology (Toomey et al. 2017) and environmental sustainability (Hering 2016). Thus, it is important that rather than each field developing separate frameworks and methodologies for guiding research and practice, efforts should be focused on aligning approaches and learnings across disparate fields and settings, with the ultimate goal of identifying a uniform scientific approach to close the know-do gap that is independent of setting and application.

It is also important for global health researchers to learn from programmes focused on the translation of innovations into commercial successes. In the US, the National Science Foundation’s Innovations Corps

(I-Corps) initiative is a public-private partnership aimed at equipping researchers in science and engineering with the skills and tools needed to translate their work from the laboratory to the marketplace (Robinson 2012). Akin to Innovation Science, the goal of this programme is to create an effective infrastructure for moving from basic discovery to a successful product.

Finally, an important goal of fostering research in implementation science and translational public health, is the full engagement of the academic enterprise in solving the pressing, practical issues of the world (El-Sadr et al. 2014). By actively seeking out collaborations with other fields within and beyond academia, implementation science can inspire an expansion of the core mission of academic institutions to include in addition to the generation of new knowledge, an emphasis on the need for engagement in taking knowledge to practice.

Environment and health: historical perspective

Human beings live in a complex environment. The importance of environmental factors in human health has been recognized since antiquity (Chen 2015). Hippocrates, in his classical writing *On Airs, Waters and Places*, emphasized the relevance of the environment to human health. He pointed out the influence of seasons and weather, location of residence, and nature of water on human health, and the occurrence of epidemics. Since ancient times, the seasonality of infectious diseases and the geographical clustering of endemic diseases have been documented worldwide. Several hypotheses had been advanced to explain the unique distribution of various diseases in time and place. The contagion theory proposed that both direct and indirect contact with sick people or animals might transmit diseases and hence both isolation and quarantine had been suggested to prevent the spread of diseases. Although they might have reduced the risk of spread of infectious diseases by ships, the strategies evolved from the contagion theory had not stopped the outbreak of many infectious diseases.

The miasma theory proposed that dirty living environments, unclean drinking water, and poor ventilation due to overcrowding might cause various diseases. This led to environmental sanitary reforms aimed at removing miasma by contributing to a cleaner environment in Europe. The hygienic movement emphasized the importance of implementing a safe drinking water supply and sewage disposal system. The *Public Health Act* enacted in Britain in 1848 was considered the first example of governmental involvement in public health affairs. However, a large outbreak of cholera still occurred in London despite its well-constructed sewage disposal system and much improved environmental sanitation in the 1850s. Through a

carefully designed survey, John Snow published his famous epidemiological study on cholera in 1855 while the germ theory was still in its infancy. He identified the consumption of contaminated drinking water as the cause of the cholera outbreak. The removal of the handle which pumped contaminated water ‘magically’ prevented the spread of the disease. The relocation of sources of drinking water successfully controlled the cholera outbreak. This was a pioneering epidemiological study in the identification of environmental factors in a disease outbreak.

In late nineteenth century, the development of germ theory led to the discovery of many specific infectious agents for human diseases. It also led to the development of several drugs for treatment of diseases, and improvements in sanitation and disinfection to control outbreaks of diseases. Robert Koch’s postulates, which emphasized a one-to-one relationship between cause and disease, were well accepted as criteria for the identification of causal agents of infectious diseases. Effective control of several infectious diseases through identification of specific agents, discovery of chemical and biological drugs, and invention of preventive and therapeutic vaccines had improved life quality and longevity of human beings. The discovery of animal reservoirs and vectors of infectious agents led to the control of vectors through environmental sanitation and disinfection. More and more biological and mechanical vectors have been identified for various viral, bacterial, and parasitic diseases since then. Control of vectors in the environment using pesticides became an important task for the prevention of infectious diseases. For example, malaria was eradicated in Taiwan through the detection and treatment of infected cases and use of the insecticide DDT. However, the widely used pesticides polluted the environment and became hazardous to wild animals and humans.

Life expectancy in most countries increased significantly after the 1950s, when conventional infectious diseases had been controlled through the widespread use of various vaccines and antibiotics. The major diseases that threaten human life have since gradually shifted from infectious to chronic non-communicable diseases. Environmental factors exposed through lifestyle habits, dietary intakes, and environmental pollution play important roles in the development of chronic diseases such as cancers, cardiovascular diseases, and neurological disorders. There are multiple risk factors in the complex multistage pathogenesis of chronic diseases. For examples,

environmental risk factors for liver cancer included hepatitis B virus, hepatitis C virus, aflatoxins, alcohol, vinyl chloride, thorium dioxide, anabolic steroids, and fine particle pollutants (Chen et al. 1997; Chen and Chen 2002; Pan et al. 2016). Some environmental pollutants may cause several chronic diseases in multiple organ systems. For example, arsenic in drinking water has been documented to induce cancers of the skin, bladder, kidney, and lung, as well as Blackfoot disease, ischaemic heart disease, stroke, hypertension, diabetes, erectile dysfunction, mental retardation, neurological disorder, cataract, pterygium, fungal infection, chronic kidney disease, and hepatitis and cirrhosis (Chen 2014; Hsu et al. 2016a, 2016b, 2017). As most chronic diseases have a multistage pathogenesis with a multifactorial aetiology without a unique one-to-one with a specific agent, the classical Robert Koch's postulates for judging the cause of disease are less applicable to chronic diseases. Bradford Hill's causation criteria including the strength, dose–response relation, temporality, specificity, and biological plausibility of the association between cause and disease have been widely adopted for the identification of causal agents for various diseases.

Endemic diseases are often characterized by their unique geographical clustering. This clustering may be associated with biological or chemical agents prevailing in local environments. Some parasitic diseases such as schistosomiasis remain endemic in areas where the ecological system maintains the life cycle of the parasites. The interruption of the life cycle through the identification and treatment of affected patients, eradication of vectors, and improvement of environmental sanitation may decrease the prevalence of these endemic parasitic diseases. Some endemic diseases such as goitre and Blackfoot disease are caused by the deficient or excessive intake of certain chemicals in the environment. The replacement of high-arsenic well water with low-arsenic surface water had decreased the occurrence of Blackfoot diseases in southwestern Taiwan. The endemic goitre caused by low dietary intake of iodine was effectively prevented by the national salt iodization programme in Taiwan.

There has been a long-standing recognition that the workplace environment can induce occupational diseases. Bernardino Ramazzini published his seminal treatise on diseases of workers. Scrotum cancer had long been considered a disease of chimney sweeps. The poor working environment in the nineteenth century sparked reform attempts in Europe,

but specific regulations to protect workers against occupational diseases were mostly implemented in the twentieth century.

Occupational hazards may spread from the workplace to its adjacent environments. For example, a major gas and chemical leak incident in a pesticide plant in Bhopal, India in 1984, and the 1986 accident at the Chernobyl nuclear power plant in Ukraine resulted in environmental disasters. In addition to the immediate casualties, both events also increased the risk of a number of chronic diseases in residents living in the vicinity. The health hazards induced by long-term exposure to industrial wastes are usually more insidious than those resulting from acute environmental disasters. Environmental pollution by industrial waste has been well documented to cause Itai-itai disease and Minamata disease in Japan. Chronic poisoning by heavy metals in industrial waste has become an important issue in environmental health. Soil and water contamination by widely used agricultural chemicals have brought significant threats to human health, wild animal life, and ecological sustainability. Air pollution has increased the risk of pulmonary diseases including asthma, chronic bronchitis, ischaemic heart disease, lung cancer, and liver cancer (Pan et al. 2016).

Natural disasters including snow-storms, hurricanes, floods, sand-storms, volcano eruptions, and forest fires have had serious consequences for public health. Other environmental disasters including earthquakes, tsunamis, and landslides are also detrimental to human health. The explosions that occurred at the Fukushima nuclear power plants in the aftermath of the major earthquake and tsunami in Fukuoka, Japan in 2011, resulted in a multiple environmental disaster. In addition to the heavy immediate casualties, natural environmental disasters threaten the function and efficiency of food, water, and electricity supply systems, ambulance and healthcare systems, sewage and waste disposal, and the control of infectious diseases. Protecting public health through proper environmental management is becoming a lasting challenge.

Causes of human diseases: host–agent interaction in the environment

Both host and environmental factors are involved in the development of human diseases, and the relative importance of environmental to host factors varies as a continuous spectrum for different diseases. Environmental factors seem to play a small role in the development of genetic diseases compared with infectious diseases or accidents. However, exposure to environmental factors may trigger the clinical manifestation of genetic diseases such as phenylketonuria and glucose-6-phosphate dehydrogenase deficiency. Environmental influences on human health are exerted through exposures to physical, chemical, and biological risk factors, and through related changes in human behavioural responses to those factors. The World Health Organization has released a country-by-country analysis of the impact of environmental factors on health (Pruss-Ustun et al. 2016). These data show that environmental risks accounted for a large fraction (23%) of the global burden of deaths and diseases. Environmental impacts on health were uneven across life course and gender. Low- and middle-income countries had the greatest share of environmental disease burden. Total environmental deaths remained unchanged from 2002 to 2012 with a strong sift to non-communicable diseases, and the evidence on quantitative links between health and environment has increased. Global health could be improved by reducing environmental risks including pollution, hazards in the work environment, ultraviolet radiation, noise, agricultural risks, climate, and ecosystem change. Proper environmental management is the key to prevent the proportion of all illnesses which are directly caused by environmental factors.

Human beings live in environments with many causes of diseases as shown in Table 7.1.1. Environmental causes for human diseases include physical, chemical, and biological agents. The physical component includes non-ionizing and ionizing radiation, noise, vibration, pressure, humidity, temperature, earthquakes, landslides, typhoons and hurricanes, and snow-storms and sand-storms. Ionizing radiation includes alpha and beta particles, gamma rays, and X-rays. Ionizing radiation may induce spontaneous abortion, congenital malformation, cancers, and haematopoietic disorders through its effects causing DNA damage and chromosomal aberrations. Non-ionizing radiation includes ultraviolet rays, visible light, infrared rays, microwaves, and electromagnetic fields. Ultraviolet rays may induce skin cancer and cataract; while electromagnetic fields may induce some cancers. The chemical component includes heavy metals, organic solvents,

agricultural chemicals, polycyclic hydrocarbons, and chlorinated organic compounds. Their health effects may be classified as acute, subacute, and chronic toxicity, carcinogenicity, mutagenicity, and teratogenicity. Some chemicals may persist in the environment and result in bioaccumulation. The biological component includes viruses, bacteria, fungi, parasites, allergens, arthropods, as well as plant and animal toxins. A number of infectious diseases of various organ systems are caused by biological agents. In addition to the acute and subacute symptoms and signs, these infectious agents may also induce chronic diseases such as cancers of the nasopharynx, stomach, liver, bladder, cervix, uteri, and lymphoid and soft tissue (Chen et al. 2014), pulmonary diseases, cardiovascular diseases, as well as neurological disorders.

Table 7.1.1 Environmental components of causes for human diseases

Component	Category
Physical	Ionizing radiation (α-particles, β-particles, γ-rays, X-rays)
	Non-ionizing radiation (ultraviolet rays, visible light, infrared rays, microwaves, electromagnetic fields)
	Noise
	Vibration
	Pressure
	Humidity and temperature
	Earthquakes and landslides
	Typhoons and hurricanes
	Snow-storms and sand-storms
Chemical	Heavy metals
	Organic solvents
	Agricultural chemicals
	Polycyclic hydrocarbons
	Chlorinated organic compounds
Biological	Viruses
	Bacteria
	Fungi
	Parasites
	Allergens
	Arthropods
	Animal and plant toxins

Host components in response to environmental components are also important in the determination of a number of human diseases as shown in Table 7.1.2. The genetic component includes a single gene for autosomal, X-

linked, Y-linked, and mitochondrial diseases, multiple genes for common diseases such as cancers and cardiovascular diseases which run in the family, and chromosomal aberrations. There also exist gene–gene interaction and gene–environment interaction in the development of human diseases. Genetic effects may be modified by environmental factors, and environmental factors may cause genetic damages and mutations. The behavioural component includes substance use, dietary intake, personal hygiene including hand-washing and safe sex, health promotion and disease prevention practice, transportation safety practice, occupational protection practice, sports and exercise, personal communication and networking, and response to stressful life events. All these behavioural components play very important roles in the prevention of environmental health hazards. For example, using cleaner fuel such as gas or electricity, using better cooking devices, improving ventilation, or keeping children away from smoke could reduce environmental risk of respiratory infections and diseases among women and children. Enforcement of helmet and seat belt laws may significantly decrease the mortality from motor vehicle accidents. The social component of human diseases includes built environments, occupational settings, agricultural methods and irrigation schemes, transportation systems, water supply systems, sewage and waste disposal, schooling systems, healthcare systems, social welfare and criminal prevention systems, anthropogenic climate changes, and ecosystem degradation. The improvement in environmental hygiene and public health systems has increased the global health status and life expectancy significantly in the last decades.

Table 7.1.2 Host components of causes for human diseases

Component	Category
Genetic Behavioural	Single gene (autosomal, X-linked, Y-linked, mitochondrial dominant/recessive)
	Chromosomal aberration
	Multiple genes (gene–gene and gene–environment interactions)
	Substance abuse (alcohol, tobacco, betel, drugs)
	Dietary intake (malnutrition, overnutrition)
	Personal hygiene and safe sex Health promotion and disease prevention practice Transportation safety practice (helmet and seat belt)
	Occupational protection practice
	Sports and exercise
	Personal communication and networking
	Stressful life events
Social	Housing and home safety
	Water supply systems
	Sewage and waste disposal
	Transportation systems
	Agricultural and irrigational methods
	Working environment
	Industrial hygiene and safety
	Schooling systems
	Healthcare systems
	Anthropogenic pollution and climate changes
	Ecosystem degradation

Several causal models have been proposed to describe the interaction between host and environment components in human health (Chen 2015).

The traditional epidemiological triangle model emphasizes the equal importance of host, agent, and environment, which are located in three angles of the epidemiological triangle. This causal model emphasizes the health effects of a specific agent, especially infectious agents, may be modified by both host and environment factors. Host factors may include the biological, sociodemographic, and behavioural characteristics including individual susceptibility and immunity, age, gender, race, socioeconomic status, occupation, genetic composition, body mass index, dietary intake, lifestyle habits, personal hygiene, and social activities. Environmental factors include living and working environments such as family, school, workplace, recreation, and healthcare place, where both agent and host interact. The disease agent may spread and transmit in the environment and affect susceptible individuals. Various strategies to prevent the occurrence of the disease caused by the agent may be developed through the understanding of the epidemiological triangle model. The agent may be controlled through disinfection and sterilization, antibiotic or antiviral treatment, intervention of drug resistance, and environmental sanitation. Active and passive immunization, improvement in nutritional status, optimal rest and exercise, immunomodulation, chemoprevention, and other host factors may be strengthened to reduce the risk of disease occurrence. The environment condition may be improved to prevent the occurrence of diseases through clean housing and workplaces, safe water and food supply, hygienic sewage and waste disposal, and others.

The epidemiological triangle model emphasizes the unique causal agent of a specific disease. This model is most appropriate for infectious diseases because the infectious agent is the necessary cause of a given infectious disease, even though the infectious agent may not be sufficient to cause the given disease. For many infectious agents, not all infected individuals will develop the disease. The one-to-one causal relation between agent and disease may not be observed under this circumstance. The triangle model is not appropriate for most chronic non-communicable diseases. Most chronic diseases have multiple causes. A single agent is neither necessary nor sufficient to cause the disease. The ecological wheel model was proposed to emphasize the host–environment interaction in the determination of human health. The ecological wheel model includes an axle (host component) surrounded by a tyre (environmental component). A disease may be caused by many environmental and host factors which are neither necessary nor

sufficient causes. They are considered as contributory causes of the disease. No unique single agent is specified for a disease in this model. The environmental component included various physicochemical, biological, and social environments just described. The host component included the genetic composition located in the core surrounded with individual immunity, lifestyle, personality, dietary intake, and social networking. The ecological wheel model emphasizes the importance of ecological balance in the maintenance of the health status of a host. The relative importance of host and various environment factors varies by diseases. For example, genetic factors are most important for the highly inheritable diseases; the biological environment for various infectious diseases; and the social environment for accidents. This casual model also stresses the interactions among host and various environments.

Neither the epidemiological triangle nor the ecological wheel takes the time dimension of disease development into consideration. The natural history of both acute and chronic diseases follows a specific temporal sequence. This usually starts from the contact of causal agent(s) with target cells, through the structural and functional changes in affected cells, the proliferation of causal agents or transformed cells, the development of lesions in target tissues or organs, the onset of clinical symptoms and signs, to the development of systemic illness. There are various agents and environment factors involved at different stages of the pathological progression. For example, the multistage process of carcinogenesis may be classified into initiation, promotion, progression, invasion, and metastasis. The development of atherosclerotic diseases includes stages of initial lesion, fatty streak, intermediate lesion, atheroma, fibroatheroma, complicated lesions, and clinical manifestation. An evolutional spiral model has been proposed to describe the disease causation through host–environment interactions over the entire natural history of the disease (Chen 1999). At the initial stage, both cause and molecular or cellular change are simple and microscopic, and the causal relationship tends to be one-to-one. With disease progression, however, the affected lesions keep expanding like a spiral with more and more complicated causal interactions between host and environment components at different stages.

The evolutional spiral model is most appropriate for the description of multistage pathogenesis of a disease with a multifactorial aetiology. As shown in Figure 7.1.1, the development of hepatocellular carcinoma (HCC)

is a multistage process with the involvement of multiple risk factors. There are many causes of HCC including hepatitis B virus (HBV), hepatitis C virus (HCV), aflatoxins, alcohol, tobacco, non-alcoholic fatty liver disease, diabetes mellitus, haemochromatosis, alpha 1-antitrypsin deficiency, and others. The exposure to causal agents may lead from mutations or epigenetic alterations of affected hepatocytes, through liver inflammation, chronic hepatitis, liver fibrosis, and cirrhosis, to HCC. During the hepatocarcinogenic process, the affected target starts from molecules and expands to cells, tissues, and organs like a spiral with more and more contributory causes involved to drive the progression of the disease. In addition to exposure to various chemical carcinogens, the inadequate intake of micronutrients including carotenoids and selenium is also associated with an increased risk of HCC. Host factors including humoral and cellular immunity, xenobiotic metabolism, hormones, and susceptibility genotypes can modify the risk of HCC development. Healthcare factors including immunization, antiviral therapy, liver disease screening, and other clinical interventions may be used to stop or slow the occurrence or recurrence of HCC.

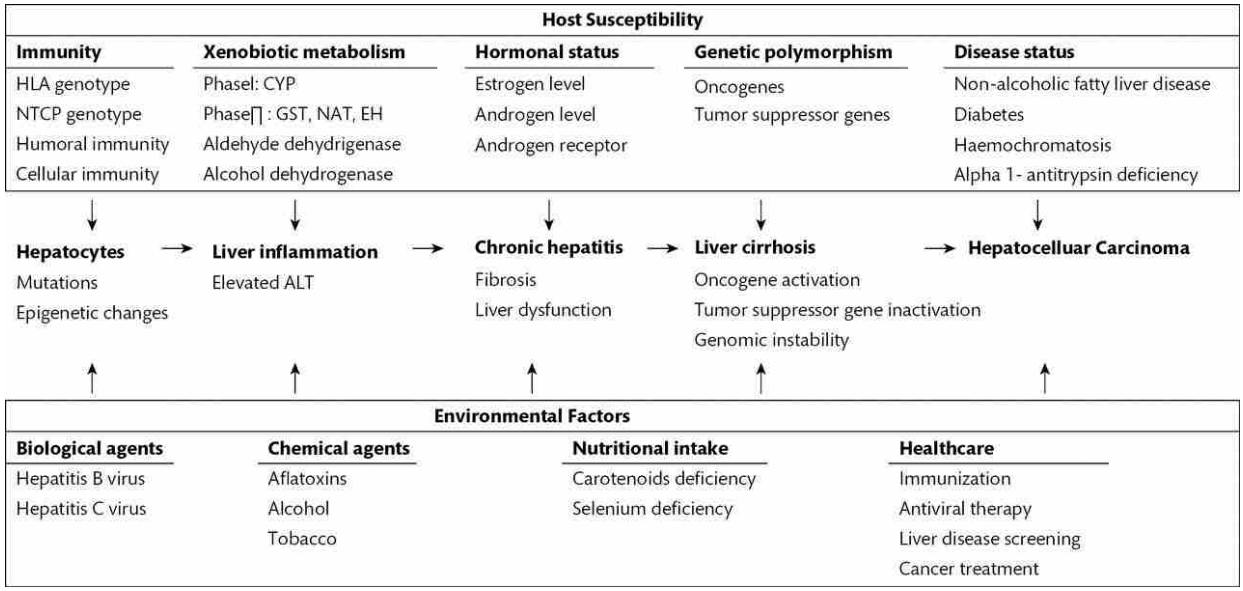

Fig. 7.1.1 Multistage hepatocarcinogenesis with a multifactorial aetiology.

Ecological studies: identification of environmental health hazards at aggregate level

Geographical clustering of endemic diseases in a small area is the most important characteristic of environmental health hazards. An extremely high prevalence of an endemic disease in a confined area should always lead to a search for unique environmental risk factors. Ecological studies are often used to compare the morbidity or mortality of environmental disease between endemic and non-endemic areas. In ecological studies, aggregate attributes such as the morbidity of residents in exposed and unexposed areas, rather than individual attributes such as the health status of exposed and unexposed subjects, are analysed and compared. Ecological studies tend to compare health indices in areas with and without the environmental exposure, or to examine quantitatively the correlation between health indices and the magnitude of environmental exposure in many areas. Some environmental characteristics or comorbidity rates may be used as surrogate indicators of the causal agents to elucidate the relation between the disease risk and the causal agent. The interpretation of ecological studies may be limited by the potential existence of ecological fallacy, when the agent–disease correlation observed at the aggregate level may not consistently be found at the individual level. However, ecological studies are frequently used to explore the environmental component of causes for human diseases.

As an illustrative example, Blackfoot disease is an endemic peripheral vascular disorder confined to a limited area on the southwest coast of Taiwan. Clinically the disease starts with numbness or coldness of one or more extremities and intermittent claudication, which progresses to black discoloration, ulcer, and gangrene. In end stages of the disease, spontaneous amputation of the distal parts of the affected extremities is common. The disease was hyperendemic in four neighbouring townships in southwestern Taiwan. As the water from shallow wells (6–8 metres in depth) in this area had high salinity, residents in some villages had started to use water from artesian wells (100–200 metres deep) since the 1920s. The use of artesian well water was found to be associated with the occurrence of the Blackfoot disease, and water samples from artesian wells of the endemic area were found to have high arsenic concentrations, which ranged from 0.35 to 1.14 mg/L.

Based on the analysis of mortality data, residents in the endemic area of Blackfoot disease had significantly elevated mortality from cancers of the skin, bladder, kidney, lung, and liver as shown in Table 7.1.3. Compared with the general population in Taiwan, the age-standardized mortality ratios for cancer of the bladder, kidney, skin, and lung were threefold or greater among male and female residents in the endemic area (Chen et al. 1985), suggesting arsenic in artesian water may cause these cancers as well as Blackfoot disease. As the four townships in this endemic area had different prevalences of Blackfoot disease, cancer mortality was further compared among townships. There was a trend that the higher the Blackfoot disease prevalence of a township, the greater the age-standardized mortality ratios for cancers of the skin, bladder, kidney, and lung.

Table 7.1.3 Age-standardized mortality ratios[1] of skin and internal cancers in four townships of arseniasis-endemic area in southwestern Taiwan by Blackfoot disease prevalence

Cancer	Gender	Blackfoot disease endemic area	Township by Blackfoot disease endemicity[2]			
			Very high	High	Medium	Low
Skin	Male	5.3	8.4	8.3	5.3	1.3
	Female	6.5	6.8	15.7	3.6	1.9
Bladder	Male	11.0	13.8	15.6	10.7	6.1
	Female	20.1	38.0	34.6	16.1	5.6
Kidney	Male	7.7	14.0	12.4	8.2	4.8
	Female	11.2	14.7	22.5	8.5	3.2
Lung	Male	3.2	3.8	5.3	2.6	1.7
	Female	4.1	6.3	6.8	3.3	1.9
Liver	Male	1.7	1.6	1.9	1.7	1.6
	Female	2.3	1.8	2.3	2.5	2.4

[1] Mortality rates of general population in Taiwan were used as the standard rates to calculate standardized mortality ratio (Taiwan = 1.0).

[2] Four townships including Peimen, Hsuehchia, Putai and Ichu with Blackfoot disease prevalence of 5.67, 3.87, 2.02 and 0.64 per 1,000, respectively. Age-standardized mortality ratios were calculated for males and females, respectively.

Source: data from Chen CJ et al., Malignant neoplasms among residents of a Blackfoot disease-endemic area in Taiwan: High-arsenic artesian well water and cancers, *Cancer Research*, Volume 45, pp. 5895–5899, Copyright © 1985 American Association for Cancer Research.

As 84 villages in these four townships also had different prevalences of Blackfoot disease and used different types of well water, more refined analyses of cancer mortality at the village level were carried out. A significant dose–response relation between the prevalence of Blackfoot disease and the age–sex-standardized mortality ratios for cancers of the skin, bladder, kidney, lung, and liver was observed at the village level as shown in Table 7.1.4. Furthermore, biological gradients of cancer mortality were also found by the type of wells used as drinking water source with the highest

cancer mortality in villages where only artesian wells were used and the lowest in villages which used only shallow wells. As both Blackfoot disease and artesian well use were significantly associated with the arsenic in drinking water, they were used as the surrogate environmental variable for arsenic exposure. It was thus implied that arsenic in drinking water might increase the risk of skin and internal cancers. However, the best way to assess the cancer risk associated with arsenic in drinking water is to obtain the arsenic levels in drinking water from wells.

Table 7.1.4 Age-sex-standardized mortality ratios[1] of skin and internal cancers in 84 villages of arseniasis-endemic area in southwestern Taiwan by Blackfoot disease prevalence and drinking water source

Cancer	Village by Blackfoot disease endemicity[2]			Village by types of wells as major drinking water source[3]		
	High	Medium	Low	Artesian only	Both	Shallow only
Skin	11.2	6.5	2.2	10.9	6.5	2.2
Bladder	40.3	17.2	3.8	26.3	11.2	4.5
Kidney	14.9	7.7	3.2	9.2	7.5	3.3
Lung	6.2	3.1	1.8	4.6	2.8	1.8
Liver	3.0	1.5	1.3	2.0	1.8	1.4

[1] Mortality rates of general population in Taiwan were used as the standard rates to calculate standardized mortality ratio (Taiwan = 1.0).

[2] A total of 84 villages were classified into three groups by Blackfoot disease prevalence: 0, 0.1–5.0 and >5.0 per 1,000, respectively.

[3] A total of 84 villages were classified into three groups by type of wells used as major drinking water source: artesian wells only, both artesian and shallow wells, and shallow wells only.

The arsenic levels in water of shallow and artesian wells in 42 villages of the Blackfoot disease endemic area were available for further analysis of the association between arsenic in drinking water and cancer mortality. The age-adjusted morality for various cancer sites and the average concentration of

arsenic in water of wells in each village were derived. As shown in Table 7.1.5, there was a significant dose–response relation between arsenic level in well water and age-adjusted mortality for cancers of the bladder, kidney, lung, skin, and liver in both males and females, and prostate cancer in males at the village level (Chen et al. 1988a). In these 42 villages, a significant dose–response relation was also observed between level of arsenic in well water and age-adjusted mortality for cardiovascular diseases and peripheral vascular diseases at the village level for both males and females (Wu et al. 1989).

Table 7.1.5 Age-standardized mortality (per 100,000) from skin and internal cancers in 42 villages of arseniasis-endemic area in southwestern Taiwan by arsenic level in well water

Cancer	Gender	Village by arsenic level in well water			General population in Taiwan
		0.60+	0.30–0.59	<0.30	
Skin	Male	28.0	10.7	1.6	0.8
	Female	15.1	10.0	1.6	0.8
Bladder	Male	89.1	37.8	15.7	3.1
	Female	91.5	35.1	16.7	1.4
Kidney	Male	21.6	13.1	5.4	1.1
	Female	33.3	12.5	3.6	0.9
Lung	Male	87.9	64.7	35.1	19.4
	Female	83.8	40.9	26.5	9.5
Liver	Male	68.8	42.7	32.6	28.0
	Female	31.8	18.8	14.2	8.9
Prostate	Male	8.4	5.8	0.5

In another large-scale ecological correlation study on age-adjusted cancer mortality of 314 precincts and townships in Taiwan (Chen and Wang 1990), the arsenic level in water of 83,656 wells was tested to derive the average arsenic level in well water in each precinct or township. Both cancer deaths and mid-year population in all study precincts and townships were obtained from the national death certification and household registration system. Based on the weighted multiple regression analysis, there were significant correlations between the average arsenic level in well water and the age-adjusted mortality rates of cancers of the liver, nasal cavity, lung, skin, bladder, kidney, and prostate at the precinct/township level. The increase in age-adjusted mortality per 100,000 person-years for every 0.1 ppm increase in arsenic level of well water for cancers of the liver, nasal cavity, lung, skin, bladder, and kidney, respectively, was 6.8, 0.7, 5.3, 0.9, 3.9, and 1.1 for males and 2.0, 0.4, 5.3, 1.0, 4.2, and 1.7 for females, after adjustment for indices of industrialization and urbanization. The increase in prostate cancer mortality for every 0.1 ppm increase in arsenic level in well water was 0.5 per 100,000 person-years. In these ecological correlation studies, both disease risk and environmental exposure were measured at a group (village or precinct/township) level. There exist potential ecological fallacies c and confounding effects of extraneous factors such as prevalence of cigarette smoking, alcohol drinking, environmental pollution, viral hepatitis, and others. The findings of ecological correlation studies have to be further validated by studies at the individual level.

Ecological correlation studies have also been carried out to imply possible causal associations between infectious agents and cancer (Chen et al. 2014). The similarity in geographical variation in prevalence of oncogenic infectious agent and incidence of specific cancer was observed for HBV/HCV and HCC, herpesvirus and Kaposi’s sarcoma, human T-cell leukaemia virus and leukaemia, liver fluke and cholangiocarcinoma, as well as *Helicobacter pylori* and stomach cancer. For example, the incidence of liver cancer and the prevalence of HBV and HCV infection are extremely high in the East, Southeast and Central Asia, and the sub-Saharan Africa. But the etiological proportion of liver cancer attributable to HBV and HCV varies in different countries and regions. HCV is more prevalent in Japan and Central Asia, and HBV is more prevalent in Taiwan, Southeast Asia, and China. Among townships in Taiwan, a significant ecological correlation between the HCC mortality and the prevalence of chronic HBV infection

was also observed. These ecological study findings suggest the importance of chronic HBV and HCV infection in the development of HCC. As around 75% of global liver cancer cases are caused by HBV and HCV. Thus, control of viral hepatitis may significantly reduce the burden of HCC globally (Chen 2018).

Cross-sectional surveys and longitudinal studies: assessment of environmental health hazards at the individual level

Several different study designs have been applied to assess the environmental health hazards at the individual level as shown in Table 7.1.6. Based on the time of the collection of disease risk (outcome) and environmental exposure (cause) data, they may be classified into cross-sectional and longitudinal studies. Cross-sectional studies collect the data on disease and exposure at the same time. The most common type of cross-sectional studies is the environmental health survey, in which participants are enrolled from exposed and unexposed areas to collect the information on health status, exposure to environmental factors, and potential confounding factors. Morbidity estimates from cross-sectional surveys represent disease prevalence rather than incidence. As the disease and exposure data are collected simultaneously, the causal temporality of disease and exposure needs further validation. If the environmental exposure is quite consistent over a long period of time before the onset of the disease, the causal temporality may be considered correct. Longitudinal studies may be further classified into case–control and cohort studies according to the enrolment of study participants. Conventional case–control studies recruit incident cases and matched controls from healthcare institutions or community, and collect the history of exposure to environmental factors through questionnaire interviews or biomarker tests. While the causal temporality is accounted for, the information on environmental exposure history may be subject to recall loss or bias and biomarkers may not reflect a long-term exposure before the disease onset. If there were detailed records of exposure history or biomarkers of long-term exposure, the biases may be reduced significantly. Conventional cohort studies recruit exposed and unexposed healthy participants from community or workplace, and follow the cohort until an adequate proportion of participants develop the disease under study. While

there is no bias of the exposure information, it may be limited by participants being lost to follow-up and resulting in the bias of disease ascertainment. If databases of disease registration, death certification, or health insurance were available, the loss to follow-up may be solved through computerized linkage with these databases.

Table 7.1.6 Major study designs of investigation on environmental health hazards at individual level

Temporality between disease and exposure	Collection of disease and exposure data	Study subjects selection	Limitations	Association estimates
Cross-sectional	Simultaneous	Random sample of population	Temporal correctness	Odds ratio
Longitudinal	Retrospective (retrieval of previous exposure)	Affected cases and unaffected controls	Recall bias	Odds ratio
Longitudinal	Prospective (follow-up of future disease)	Exposed and unexposed cohorts	Loss of follow-up	Hazard ratio

Returning to Blackfoot disease as an illustrative example, in a community-based cross-sectional survey of 40,421 residents in 37 villages in the endemic area in southwestern Taiwan, the relation between status of skin cancer and Blackfoot disease in participants, and arsenic in well water was examined (Tseng 1977). There was a significant dose–response relation between the arsenic concentration in the well water and the prevalence of skin cancer and Blackfoot disease for most age and sex groups. There was also a significant coexistence of both skin cancer and Blackfoot disease. In a community-based case–control study, a total of 353 pairs of Blackfoot disease cases and matched controls were interviewed (Chi and Blackwell 1968). The length of residing in the endemic villages was significantly associated with the risk of developing Blackfoot disease in a dose–response relation. While all 353 (100%) Blackfoot disease cases had ever used artesian well water as the principal source of drinking water during the 15 years before disease onset, only 233 (66%) matched controls had consumed artesian well water ($p < 0.001$). Blackfoot disease cases had lower

educational level and socioeconomic status than matched controls. In another case–control study on 241 Blackfoot disease patients and 759 matched healthy controls, questionnaire interviews were carried out to obtain information on the history of consuming artesian well water, diet, alcohol intake, and cigarette smoking, as well as the presence of arsenic-induced skin keratosis and cancer, and Blackfoot disease in first-degree relatives (Chen et al. 1988b). There was a significant dose–response relation between the risk of developing Blackfoot disease and the duration of consumption of artesian well water. In addition, arsenic-induced skin lesions, family history of Blackfoot disease, and undernourishment were also associated with the development of Blackfoot disease independent of the duration of consuming artesian well water.

In a cohort study of cause-specific mortality of 789 Blackfoot disease patients followed for 15 years (Chen et al. 1988b), age–sex-standardized mortality ratios were derived for Blackfoot disease patients using the mortality rates of the general population in Taiwan and the Blackfoot disease endemic area as the standard rates, respectively. As shown in Table 7.1.7, patients of Blackfoot disease had increased mortality from cardiovascular disease and cancers of the skin, bladder, lung, kidney, liver, and prostate compared to two reference populations. In another case–control study on cancers of bladder, lung, and liver in the endemic area of Blackfoot disease (Chen et al. 1986), the duration of consuming artesian well water was significantly associated with three cancers in a dose–response relation after adjustment for age and sex.

Table 7.1.7 Age-standardized mortality ratios for cancers and vascular diseases for Blackfoot disease patients in comparison with two referent populations

Disease	Standardized mortality ratio in Blackfoot disease patients	
	Taiwan population as reference[1]	Endemic area population as reference[2]
Skin cancer	28.5**	4.5*
Bladder cancer	38.8***	2.6**
Kidney cancer	19.5	1.6
Lung cancer	10.5***	2.8**
Liver cancer	4.7***	2.5**
Prostate cancer	17.3	2.7
Peripheral vascular disease	12.4***	3.5***
Cardiovascular disease	2.1***	1.6**
Cerebrovasular disease	1.2	1.1

All rights reserved. DOI: 10.1161/01. ATV.8.5.452.

A community-based health survey study was carried out in three Blackfoot disease-hyperendemic villages to examine the associations between arsenic in drinking water and various chronic diseases. A total of 1,571 residents aged over 30 years were interviewed by public health nurses, and 1,071 of them had health examinations. Residents in these villages started using artesian wells as the principal drinking source in early 1910s,

and shifted to the public water supply system using surface water from a distant reservoir in early 1970s. The arsenic level in water of artesian wells of the Blackfoot disease-hyperendemic villages was surveyed in the early 1960s. As residents in a given village shared a few wells together, the median arsenic level of the water from the shared wells was used as the level of arsenic in drinking water for residents of the village. As a participant might migrate from one village to another, a detailed life history of residence and consumption of artesian well water was obtained through a structured questionnaire interview. The cumulative arsenic exposure was derived by the formula $\Sigma (C_i \times D_i)$; where C_i was the median arsenic level in water of shared wells of a village in which the participant lived, and D_i was the duration of drinking artesian well water in the village during the consecutive period i. The average arsenic exposure level in drinking water of a participant was derived by $\Sigma (C_i \times D_i)/\Sigma (D_i)$. Residents in hyperendemic villages of Blackfoot disease had a significantly higher age-specific prevalence of diabetes mellitus (Lai et al. 1994) and hypertension (Chen et al. 1995) than residents in non-endemic areas. Furthermore, there was a significant dose–response relation between the cumulative arsenic exposure and prevalence of diabetes mellitus (Lai et al. 1994), hypertension (Chen et al. 1995), peripheral vascular disease based on Doppler ultrasonography (Tseng et al. 1996), carotid atherosclerosis based on duplex ultrasonography (Wang et al. 2002), electrocardiogram-based ischaemic heart disease (Tseng et al. 2003), cataract (See et al. 2007), and pterygium (Lin et al. 2008) as shown in Table 7.1.8. Cohort follow-up studies also found a significant biological gradient of incidence of skin cancer (Hsueh et al. 1997) and lethal ischaemic heart disease (Chen et al. 1996a) with increasing cumulative arsenic exposure.

There was another survey of well water arsenic and health status enrolling a total of 8,102 residents in four townships located in northeast Taiwan. Residents in these townships had their own tube wells in their backyards. The arsenic levels in well water of these households were tested in early 1990s. The public water supply system using surface water was introduced in this area in early 1990s, and its coverage was as high as 95% in the year 2000. There was a dose–response relation between the cumulative exposure of arsenic in well water and prevalence of cerebrovascular disease, especially cerebral infarction, which was identified from home-visit personal interviews and ascertained through the review of hospital medical records

(Chiou et al. 1997). A significant dose–response association with arsenic level in drinking water was also observed for the prevalence of chronic hepatitis or cirrhosis in participants who were seronegative for hepatitis B surface antigens (HBsAg) and antibodies against HCV (Hsu et al. 2016a, b), as well as chronic kidney disease (Hsu et al. 2017).

Table 7.1.8 Dose–response relationship between cumulative arsenic exposure and risk of various diseases. Figures are relative risks (95% confidence intervals)

Disease/cause of death	Cumulative arsenic exposure			
	Low	Medium	Medium high	High
Skin cancer[1]	1.0 (referent)	2.8 (0.3–31.9)	2.6 (0.3–22.9)	7.6 (1.0–60.3)
Hypertension[2]	1.0 (referent)	0.9 (0.2–3.3)	2.4 (0.8–6.9)	3.6 (1.4–9.6)
Ischaemic heart disease death[3]	1.0 (referent)	2.5 (0.5–11.4)	4.0 (1.0–15.6)	6.5 (1.9–22.2)
Cataract (posterior subcapsular opacity)[4]	1.0 (referent)	2.2 (0.4–12.1)	4.8 (1.0–22.2)	5.7 (1.2–26.3)
Hepatitis and cirrhosis (without chronic viral hepatitis)[5]	1.0 (referent)	1.4 (0.6–3.7)	2.2 (0.8–6.4)	3.3 (1.2–9.1)
Chronic kidney disease[6]	1.0 (referent)	1.2 (0.9–1.5)	1.4 (1.1–1.8)	1.4 (1.0–1.8)
	Low	**Medium**	**High**	
Diabetes mellitus[7]	1.0 (referent)	6.6 (0.9–51.0)	10.1 (1.3–77.9)	
Electrocardiogram-based ischaemic heart disease[8]	1.0 (referent)	1.6 (0.5–5.3)	3.6 (1.1–11.7)	
Doppler ultrasonography-based peripheral vascular disease[9]	1.0 (referent)	2.8 (0.9–9.1)	4.3 (1.3–14.5)	
Duplex ultrasonography-based carotid atherosclerosis[9]	1.0 (referent)	1.8 (0.8–3.8)	3.1 (1.3–7.4)	
Cerebral infarction[10]	1.0 (referent)	2.7 (1.2–5.8)	3.4 (1.4–8.1)	
Pterygium[11]	1.0 (referent)	3.1 (1.8–5.6)	4.1 (2.2–7.4)

Source data from: skin cancer (Hsueh et al. 1997), hypertension (Chen et al. 1995), ischaemic heart disease death (Chen et al. 1996a), cataract (See et al. 2007), diabetes mellitus (Lai et al. 1994), electrocardiogram-based ischaemic heart disease (Tseng et al. 2003), Doppler ultrasonography-based peripheral vascular disease (Tseng et al. 1996), duplex ultrasonography-based carotid atherosclerosis (Wang et al. 2002), cerebral infarction (Chiou et al. 1997), pterygium (Lin et al. 2008), cirrhosis and hepatitis (Hsu et al. 2016), and chronic kidney disease (Hsu et al. 2017).

The occurrence of cancers of cohort participants enrolled from the endemic areas of arseniasis in southwestern and northeastern Taiwan was identified and ascertained through computerized data linkage with national cancer registry and death certification profiles. A dose–response relation was observed between long-term arsenic exposure from drinking well water and incidence of urothelial carcinoma (Chiou et al. 2001) and lung cancer (Chen et al. 2004). There was a synergistic effect on the development of lung cancer for cigarette smoking and exposure to arsenic in drinking water. Based on follow-up data from northeastern Taiwan, the cumulative lifetime (35–85 years) risk of lung cancer and urothelial carcinoma was found to increase with the arsenic concentration in well water (Yang et al. 2013). The lifetime lung cancer risk for arsenic levels in drinking water of <10, 10–99, and 100+ μg/L was 7.42%, 8.99%, and 17.09%, respectively; and the corresponding lifetime risk of urothelial carcinoma was 0.29%, 1.07%, and 3.43%, respectively. It is essential to ensure accuracy in the assessment of exposure to environmental factors in all cross-sectional surveys, case–control studies, and cohort studies in order to identify and characterize the environmental health hazards efficiently and effectively. It is also important

to be aware of the possibility of temporal variations in concentration of the causal agent in various environmental media, individual variations in frequency and quantity of contact with the contaminated environmental media, and variations in detection limit of various exposure assessment methods.

As one agent may cause many diseases like arsenic in drinking water, one disease may be caused by many agents. The multifactorial aetiology of HCC have been explored by many case–control and cohort studies (Chen et al. 1997; Chen 2018). The causes of HCC include HBV and HCV. In the 1970s, coexistence of HCC and HBsAg seropositivity, the biomarker of chronic HBV infection, was observed in several cross-sectional case–control studies. In the natural history of chronic HBV infection, spontaneous seroclearance of important milestone biomarkers including hepatitis B e-antigen (HBeAg), HBV DNA and HBsAg may occur (Chen and Yang 2011). HBeAg seroclearance occurs after a period of elevation of serum level of alanine aminotransferase (ALT), a seromarker of liver inflammation. The serum HBV DNA level (viral load) may remain high or gradually decline in HBeAg-seronegative patients. Seroclearance of HBsAg may occur after the serum HBV DNA level becomes undetectable. The seroclearance of these HBV biomarkers may occur before the time of HCC diagnosis. As HBeAg, HBV DNA, and HBsAg may be serocleared gradually with increasing age, their seroprevalence at the onset of HCC is much lower than that in childhood or young adulthood. It should thus be noted that cross-sectional studies might underestimate the relative HCC risk associated with the seropositivity of HBsAg, HBV DNA, and HBeAg if HCC cases and controls were not well matched on age. This may explain the wide range of relative HCC risk for HBsAg seropositivity in various cross-sectional case–control studies.

Longitudinal cohort studies may better elucidate the HCC risk associated with these risk predictors. The causality between chronic HBV infection and HCC was first confirmed by the GECC cohort study in Taiwan (Beasley et al. 1981), the first prospective follow-up study on virus-caused human cancer. The REVEAL-HBV cohort study has documented the increased risk of HCC and cirrhosis associated with HBeAg serostatus and increasing serum HBV DNA level in HBsAg-seropositive patients (Yang et al. 2002; Chen et al. 2006; Iloeje et al. 2006). Repeated measurements of serial biomarkers during the follow-up period may help examine the causal

temporality more accurately. For example, the long-term trajectory rather than baseline levels of HBV viral load has been documented to predict HCC risk more precisely (Chen et al. 2011). There was a significant dose–response relation between HBV viral load at study entry and risk of HCC newly developed during the follow-up. However, the HCC risk significantly varied among chronic hepatitis B patients with high viral loads at study entry. The HCC risk was highest for those maintaining a high viral load during the follow-up, and lowest for those whose viral load declined significantly to low levels. In other words, the follow-up biomarkers were very useful to stratify patients into more refined HCC risk groups. It has also been well documented that seroclearance of HBV biomarkers lead to a significant decrease in HCC risk (Liu et al. 2014). These observational studies suggest the most effective and efficient way to reduce the HCC risk is to eliminate chronic viral hepatitis through hepatitis B vaccination and antiviral therapy of chronic hepatitis B and C.

Elevated serum level of aflatoxin B_1-albumin adducts at study entry was found to increase the risk of cirrhosis and HCC in patients affected with chronic hepatitis B or C in case–control studies nested in the REVEAL-HBV cohort (Chu et al. 2017; Chu et al. 2018). It is important to note that the aflatoxin exposure at study entry may predict risk of end-stage liver diseases occurring within 8 or 9 years, but not those occurring afterward. In other words, aflatoxin may be a risk predictor only at the late stage of chronic liver disease development and/or aflatoxin exposure at study entry may not reflect the exposure in the long period of follow-up. This further supports the importance of serial measurements of exposure to risk predictor in cohort studies in order to elucidate the time-dependent effect of the disease predictors.

Intervention studies: validation of environmental health hazards through preventive intervention

It is unethical to carry out experimental trials on human beings to validate the suspected effects of environmental health hazards identified from observational studies discussed earlier. However, intervention trials or programmes may be used to validate possible effects of environmental agents on disease risk by removing the exposure to agents in the

environment. Intervention trials may be classified as individual or cluster trials depending on whether individual participants or clusters such as households, schools, or communities are allocated to the intervention. Intervention trials may also be classified as controlled and uncontrolled trials depending on the inclusion of a comparable control group or not. In controlled trials, the effect of the intervention on environmental health hazards is evaluated by the comparison of disease occurrence between experimental and control groups. In uncontrolled trials, the effect of intervention is assessed by the comparison of disease occurrence of the experimental group before and after the intervention.

The implementation of a public water supply system, which used uncontaminated surface water from distant reservoirs, in the Blackfoot disease endemic area of southwestern Taiwan was started in the early 1960s and completed in the 1970s. The arsenic-induced health hazards identified from observational studies could thus be validated through the comparison of the secular changes in morbidity and mortality of arsenic-induced diseases in the endemic and non-endemic areas. In a series of studies, cause-specific standardized mortality ratios of residents in the Blackfoot disease endemic from 1971 to 2003 were calculated using the general population in Taiwan as the standard population. Cumulative sum techniques were used to detect the occurrence of changes in the standardized mortality ratios. A significant decline in mortality from ischaemic heart disease (Chang et al. 2004), renal disease (Chiu and Yang 2005), peripheral vascular disease (Yang 2006), and cancers of the lung (Chiu et al. 2004b), kidney (Yang et al. 2004), and bladder (Yang et al. 2005) was observed for both males and females in the southwestern endemic area of Blackfoot disease. A significant decline in mortality from liver cancer (Chiu et al. 2004a) and diabetes mellitus (Chiu et al. 2006) was observed for females but not males. Based on the reversibility criterion, it was concluded that associations between arsenic exposure and these diseases were very likely to be causal. Although the findings are quite consistent with observational studies mentioned earlier, there are several issues which need further clarification: (1) Classification of underlying causes of death may vary by area and time. It is necessary to examine whether the variations in the classification of underlying causes in death certificates are comparable in different areas over the study period. (2) Competing causes of death may be quite different between the endemic area and Taiwan as a whole. Arsenic has a pleiotropic health effect that induces

various cancers, circulatory diseases, diabetes mellitus, hypertension, renal disease, and so forth. A person may die with several arsenic-induced diseases. It is thus difficult to select an underlying cause of death for an arsenic-exposed person. (3) Mortality associated with a disease is a function of the incidence and fatality of the disease. High mortality may imply an increased incidence and/or an elevated fatality rate. It is better to analyse incidence rather than mortality to clarify the causal association between agent and disease. (4) Risk factors other than arsenic may be important confounding factors, such as habits of cigarette smoking and alcohol drinking, chronic viral hepatitis, and obesity. They were not taken into consideration in the mortality analysis. It is thus more convincing to compare the secular changes in the incidence of arsenic-induced diseases after the implementation of public water supply system. Furthermore, age-cohort-period analysis may also help the identification of susceptible ages at exposure to arsenic and the assessment of reversibility effect of intervention.

A nationwide vaccination programme aimed at eradicating HBV infection was launched in 1984 in Taiwan (Chien et al. 2014). It was the first universal hepatitis B vaccination programme for infants in the world. During the first 2 years (July 1984 to June 1986) of the programme, only infants born to high-risk (HBsAg-positive) mothers were vaccinated. Since July 1986, however, all new-borns were vaccinated. The programme was further extended to the preschool children who had not received vaccination as neonates since 1987. There has been a dramatic decrease in the HBsAg carrier rate and HCC incidence among children and adolescents born after 1984 demonstrating the programme not only successfully prevented the transmission of HBV but also reduced the risk of HCC (Chang et al. 1997), which is the first study to demonstrate the prevention of human cancer through vaccination. Even more striking has been the effectiveness of the national hepatitis B vaccination programme in reducing long-term risk of infant fulminant hepatitis, chronic liver disease, and HCC 30 years after its launch (Chiang et al. 2013). Through the strong evidence of a striking decline in HCC incidence of the vaccinated infants, the causal relation of chronic HBV infection with HCC is well confirmed. However, the elucidation of the failure of hepatitis B vaccination to eliminate HCC in the vaccinated birth cohort requires further study at the individual rather than national level. In a 20-year cohort study of 3.8 million vaccinees, incomplete hepatitis B immunization and maternal HBV carrier status are associated

with the vaccine failure and resulting risk of acute and chronic liver diseases (Chien et al. 2014).

Several antivirals have been approved for chronic hepatitis B therapy, Lamivudine was first approved in 1998 which was found to decrease the HCC risk of treated patients significantly with a large proportion developed antiviral-resistant YMDD mutants (Liaw et al. 2004). Newly developed antivirals for hepatitis B therapy have higher genetic barriers to induce antiviral-resistant HBV. The interferon-based therapy was the standard for chronic hepatitis C treatment before direct acting agents were launched in 2013. Several recent studies have shown the decrease in incidence of HCC in chronic hepatitis B patients treated with oral nucleoside/nucleotide analogues and in chronic hepatitis C patients who cleared HCV with direct acting agents (Chen 2018). A national programme of antiviral therapy on high-risk CHB and CHC patients was launched in October 2003 in Taiwan. A significant reduction in the burden of end-stage liver diseases through this programme has recently been documented. A total of 157,570 CHB patients and 61.823 CHC patients were treated with reimbursed antiviral therapy from 2004 to 2011. There was 22% reduction in mortality from chronic liver diseases and cirrhosis, 24% reduction in HCC mortality and 14% reduction in HCC incidence in 2008–2011 compared to the 4-year period before the programme launch, i.e. 2000–2003 (Chiang et al. 2015). The study confirmed HBV and HCV are the most important aetiology of cirrhosis and HCC in Taiwan. Recent international studies has shown the decrease in the incidence of HCC in CHB patients treated with pegylated interferon or any nucleoside/nucleotide analogues (Lin et al. 2016) or treated with entecavir or tenofovir (Papatheodoridis et al. 2017), and in CHC patients who cleared HCV with pegylated interferon with ribavirin (Huang et al. 2017) or DAAs (Ioannou et al. 2017). These studies have further confirmed HBV and HCV are the most important aetiology of cirrhosis and HCC in the world.

Before the Second World War, endemic goitre was highly prevalent in mountainous areas in Taiwan. A national survey showed a prevalence as high as 70% in some aboriginal townships in mountainous areas. The prevalence of goitre in pigs was found to be significantly higher in the goitre-endemic area than non-endemic area. It was debated whether dietary deficiency in iodine or goitrogenic foodstuff intake was the major cause of the endemic goitre. The use of iodine tablets to supplement dietary iodine intake was found to be effective in lowering the prevalence of endemic

goitre in school children, but it was considered costly and inconvenient. In order to identify an effective and efficient prevention strategy at the community level, a controlled community intervention trial on iodized salt was carried out in two townships in northern Taiwan (Chen et al. 1976). All the dietary salt used in experimental and control townships was strictly provided by the research team. Before the implementation of the community trial, the endemic goitre prevalence among schoolchildren was similarly high. One year after the trial, the prevalence of endemic goitre in the experimental township was significantly lower than in the control township. While the study did not rule out the possible effects of the intake of goitrogenic foodstuff, iodine deficiency was confirmed to be the most important risk factor for endemic goitre in Taiwan. A nationwide salt iodization programme supported by UNICEF was implemented, and the goitre prevalence has been drastically reduced since then. As there may be changes in dietary intake of iodine other than iodized salt, it is essential to monitor and adjust the level of iodine in the salt to prevent thyroid toxicity due to excessively high intakes of iodine.

Individual susceptibility to environmental health hazards: identification and application of molecular and panomic biomarkers

The risk of developing an environmental disease may vary in different persons exposed to the same environment. In other words, there exists a host variation in the susceptibility to diseases caused by environmental factors. The individual susceptibility may come from genetic or behavioural components. For example, poor nutritional status and arsenic methylation capability may modify the risk associated with arsenic-induced health hazards including cancers and cardiovascular diseases. Multiple risk factors including cigarette smoking, aflatoxin exposure, antioxidant deficiency, and serum androgen levels are all important risk factors to HBV-induced HCC. Some environmental co-factors are difficult to detect and quantify unless biomarkers are used. Many studies have been carried out in recent decades on changes in the structures and functions of molecules, cells, tissues, and organ systems in response to exposures to environmental risk factors, to ascertain if the preclinical lesions of environmental diseases could be

detected at an early stage which would allow more timely intervention. More recently, the dramatic advances in genomics, proteomics, transcriptomics, proteomics, glycomics, lipidomics, and metabolomics have enabled more extensive investigations into the genetic polymorphisms and mutations as well as epigenetic changes of host to elucidate the effects of gene–gene and gene–environment interactions more precisely.

Various biomarkers of environmental exposure, health effect, and individual susceptibility of human diseases have been identified and applied in studies on environmental health hazards. The biomarkers for the exposure to environmental factors include molecular dosimetry of internal dose and biologically effective dose. The biomarkers for the health effect include early molecular and cellular changes, altered structures and functions of target tissues and organs, and preclinical lesions. The individual susceptibility biomarkers include both genetic and acquired susceptibility. As an illustration, since the development of chronic arsenic poisoning is a multistage pathogenesis, a series of biomarkers of arsenic-induced health hazards have been developed and applied as shown in Table 7.1.9 (Chen et al. 2005). There are several biomarkers of short-term internal dose for ingested arsenic including levels of arsenic in blood, urine, hair, and finger or toenails. Arsenic in urine, hair, and nails are better biomarkers for short-term exposure than arsenic in blood. Skin hyperpigmentation and palmoplantar hyperkeratosis, characteristic dermatological lesions induced by long-term exposure to arsenic, are excellent clinical biomarkers for long-term exposure to ingested arsenic. Patients with characteristic arsenic-induced skin lesions were found to have an increased risk of Blackfoot disease, lung cancer, and urothelial carcinoma. Inorganic arsenic is methylated into monomethylarsonic acid (MMA) and then further methylated into dimethylarsinic acid (DMA) in the human body. Monocarbon metabolism is involved in the methylation of inorganic arsenic. Genetic polymorphisms of arsenic (+3 oxidation state)-methyltransferase, purine nucleoside phosphorylase, and glutathione S-transferase (GST) omega 2 are associated with the arsenic methylation capability in humans. As MMA is more toxic than DMA, the percentage of MMA in the total urinary concentration of inorganic metabolites is considered as the biomarker for biologically effective dose of arsenic exposure. It has been well-documented that the higher the MMA percentage in the total urinary level of inorganic arsenic metabolites, the higher the risk of arsenic-induced

skin cancer, bladder cancer, lung cancer, peripheral vascular disease, carotid atherosclerosis, and hypertension.

The biomarkers of molecular changes induced by ingested arsenic include plasma levels of reactive oxidants and inflammatory molecules such as chemokine C-C motif ligand 2/monocyte chemotactic protein-1. The arsenic-induced cellular changes include sister chromatid exchanges, micronuclei, and chromosomal aberrations in peripheral lymphocytes and urothelial cells; as well as chromosomal loss and gain detected by comparative genomic hybridization and loss of heterozygosity in urothelial cells. Biomarkers of subclinical changes include carotid atherosclerosis, QT prolongation, and increased dispersion detected by electrocardiogram, retarded peripheral neural conduction, and retarded neurobehavioural function. The biomarkers of individual susceptibility to arsenic-induced health hazards include genetic polymorphisms of enzymes involved in arsenic and xenobiotic metabolism, arsenic methylation, oxidative stress, and DNA repair, as well as serum levels of carotenes, homocysteine and folate, body mass index, and cigarette smoking.

Table 7.1.9 Molecular and genomic biomarkers of exposure, effect, and susceptibility of arsenic-induced health hazards

Category	Group	Biomarkers
Exposure	Internal dose	
	Short term	Arsenic in urine, hair, and nail
	Long term	Skin hyperpigmentation and hyperkeratosis
	Biologically effective dose	Monomethylarsonic acid in urine
Effect	Molecular changes	Reactive oxidants in blood
		Inflammatory molecules in blood
	Cellular changes	Sister chromatid exchanges
		Micronuclei
		Chromosomal aberrations in target cells
		Chromosomal loss/gain and loss of heterozygosity in target cells
	Subclinical changes	QT abnormality in electrocardiogram
		Carotid atherosclerosis
		Retarded peripheral neural conduction
		Retarded neurobehavioural function
Susceptibility	Genetic susceptibility	Arsenic and xenobiotic metabolism enzymes
		Arsenic methylation enzymes
		DNA repair enzymes
		Oxidative stress-related enzymes
	Acquired susceptibility	Serum carotenes level Serum folate level Serum homocysteine level Body mass index Cigarette smoking

In the multistage hepatocarcinogenesis of chronic hepatitis B, there are many other risk factors that modify the risk of developing HBV-induced HCC (Chen and Chen 2002). Biomarkers associated with HBV-induced HCC are shown in Table 7.1.10. HBV infection markers include HBsAg, HBeAg, antibodies against hepatitis B core antigen (anti-HBc), antibodies against HBsAg (anti-HBs), as well as serum levels of HBV DNA (viral load), HBsAg, and anti-HBc. Different HBV infection markers have different associations with the development of HCC. In addition to the seropositivity of HBsAg and HBeAg, serum HBV DNA level is associated with an increasing risk of cirrhosis and HCC in a dose–response relation (Chen et al. 2006; Iloeje et al. 2006). Different genetic characteristics of HBV are also associated with different risk of liver cirrhosis and HCC. The genotype C, basal core promoter A1762T/G1764A mutant, and pre-S mutant of HBV are significantly associated with an increased risk of liver diseases; while the precore stop codon G1896A mutant is associated with a decreased risk (Yang et al. 2008). Both quantitative and qualitative characteristics of HBV are important in the development of HCC.

Table 7.1.10 Molecular and genomic biomarkers associated with hepatitis B virus-induced hepatocellular carcinoma

Category	Group	Biomarkers
Exposure	Hepatitis B virus	HBsAg/HBeAg seropositivity Serum level of HBV DNA (viral load) and HBsAg
		HBV Genotype
		HBV Mutants
		Serum level of antibody against HBV core antigen (anti-HBc)
	Aflatoxins	Urinary level of aflatoxin metabolites and guanine adducts
		Serum level of aflatoxin albumin adducts
	Tobacco	DNA adducts of 4-aminobiphenyl and polyaromatic hydrocarbons in hepatocytes
Effect	Asymptomatic carrier	Elevated serum level of alanine aminotransferase
	Chronic hepatitis	Serum ALT and AST level Fibrosis detected by biopsy/Fibroscan
	Cirrhosis	Child-Pugh score (albumin, bilirubin, prothrombin time, ascites, encephalopathy)
	HCC	Serum alpha-fetoprotein level Histopathological confirmation by biopsy Imaging by ultrasound, CT scan, and MRI
Susceptibility	Immunity	Anti-HBs-seropositivity
	Hormonal status	Serum levels of androgen and oestrogen
	Genetic polymorphisms	HBV receptor (sodium taurocholate co-transporting polypeptide) Human leukocyte antigens Xenobiotic metabolism enzymes
		DNA repair enzymes
		Hormone metabolism enzymes and receptors
	Nutritional intake	Serum levels of carotenoids and selenium

Dietary exposure to aflatoxins and habits of cigarette smoking and alcohol drinking have been found to increase the risk of hepatitis B-induced HCC. Due to the difficulties in measuring dietary intake of trace amount of aflatoxins and environmental exposures to tobacco smoke, several biomarkers are used for the molecular dosimetry of aflatoxin and tobacco smoke exposures. Aflatoxin metabolites in urine is used as a biomarkers for internal dose, and macromolecular adducts of aflatoxin as biomarkers for biologically effective dose. The hepatic DNA adducts of 4-amino-biphenyls and polyaromatic hydrocarbons are used to measure the biologically effective dose of exposures to tobacco smoke, while DNA and albumin adducts of aflatoxin B_1 were used as biomarkers of biologically effective dose. There is a dose–response relation between exposure to hepatotoxins and HCC risk. There are significant synergistic effects on HCC between chronic hepatitis B and environmental hepatotoxins. The hepatocarcinogenesis progresses from asymptomatic carrier status, chronic hepatitis, cirrhosis, to HCC. There are several biomarkers which may be used for the detection of various precancerous lesions.

The effect of environmental hepatotoxins on the HBV-induced HCC is modified by genetic polymorphisms of enzymes related to xenobiotic metabolism. Genetic polymorphisms of cytochrome P450 (CYP) enzymes 1A1 and 2E1, GST M1 and T1, N-acetyltransferase 2 were found to modify HBV-induced HCC risk associated with aflatoxin and tobacco exposure. For example, a significant dose–response relation between HCC risk and serum level of aflatoxin B_1 albumin adducts is observed in chronic HBV carriers with null genotype of GST M1 or T1, but no dose–response relation is observed for carriers with wild genotypes (Chen et al. 1996b). The dose–response relation between elevated serum testosterone level and HCC is much more obvious for chronic hepatitis B patients with the high-risk genotype of androgen receptor (Yu et al. 2000). Furthermore, the combination of putative high-risk genotypes of androgen receptor, CYP17, and steroid 5α-reductase is associated with highly elevated risk of hepatocellular carcinoma suggesting a significant additive effect of gene–gene interaction in the human host (Yu et al. 2001). The associations between HBV-induced HCC and low serum levels of micronutrients including carotenoids and selenium were modified by genetic polymorphisms of xenobiotic metabolism enzymes. The interactive effects

on human health between biological and chemical agents in the environment are complicated and deserve scrutiny.

Risk assessment of environmental human diseases: standards of arsenic in drinking water and risk calculators for hepatocellular carcinoma in viral hepatitis patients

In order to assure the safety of drinking water to protect public health, norms for drinking-water quality were initially recommended by World Health Organization in 1958. The *International Standards for Drinking-Water* established 0.20 mg/L as an allowable concentration for arsenic. The standard was re-evaluated and reduced to 0.05 mg/L in 1963. It was maintained as the 'Guideline Value' of World Health Organization in 1984, and many countries kept this as the national standard or an interim target. In the United States, congress directed Environmental Protection Agency to revise the standard in 1986. According to the 1993 edition of the *WHO Guidelines for Drinking-Water Quality*, inorganic arsenic was classified as a documented human carcinogen and 0.01 mg/L was established as a provisional guideline value for arsenic. The mortality from cancers of the liver, lung, and urinary bladder from exposure to arsenic in the drinking water of 42 villages in southwestern Taiwan was intensively analysed (Morales et al. 2000). The original standard of arsenic in drinking water (0.05 mg/L) was found to be associated with a substantial increased risk of cancer and is not sufficiently protective of public health. Based on the risk assessment and cost-effectiveness analysis, a new maximal contamination level of 0.01 mg/L became effective in February 2002, and was complied with in 2006 in the United States. Several hundred million people in the world are exposed to ground water containing arsenic level higher than 0.01 mg/L. Strategies for the mitigation of chronic arsenic poisoning from drinking water may include the elimination of wells with high-arsenic water, implementation of clean water supply system to areas where the arsenic concentration in drinking water is high, monitoring of arsenic levels in agricultural products irrigated by high-arsenic water, identification, and health surveillance of exposed population, as well as detection and management of preclinical and clinical outcomes of poisoned victims.

The prediction of disease risk is important for the planning and evaluation of public health programmes aimed at controlling the disease. Risk calculators of many diseases, especially cardiovascular diseases, have been developed and widely applied. As there are many risk predictors for most diseases, it is necessary to integrate several predictors into one measure of absolute risk using a regression model. Uncertainty about clinical interpretation of a single abnormal biomarker may be improved by the development of risk calculators based on the combination of multiple biomarkers. The risk calculator also allows for appropriate recognition of clinically important risk in persons with several but seemingly marginal risk factors that individually may otherwise not raise clinical concerns.

As described earlier, there are several risk predictors of HCC in patients affected with chronic hepatitis B. Based on the long-term follow-up findings of REVEAL-HBV study, long-term risk of cirrhosis and HCC have been developed and validated (Yang et al. 2010; Lee et al. 2013; Chen et al. 2015). For example, a nomogram of predicted HCC risk for chronic hepatitis B patients is shown in Figure 7.1.2. Risk predictors included in this nomogram were gender, age, family history of HCC, alcohol intake, serum ALT level, HBeAg serostatus, and serum HBV DNA level. Integer risk scores were assigned to different categories of various risk predictors. The nomogram showing 5- and 10-year cumulative risk of HCC by sum of risk score. A 64-year-old man with a family history of hepatocellular carcinoma, a habit of alcohol intake, a serum ALT level > 45 IU/L, and an HBeAg-seropositive status has a risk score of 2 + 6 + 2 + 2 + 2+ 6 = 20. His cumulative risk of developing HCC after 5 and 10 years is estimated at around 90% and 100%, respectively. The REACH-B risk calculator of HCC was derived from community-based REVEAL-HBV cohort and internationally validated by hospital cohorts of chronic hepatitis B patients from Hong Kong and South Korea (Yang et al. 2011). This HCC risk calculator was found to have a high sensitivity, specificity, and discriminating capability. These HCC risk calculators may be used to assess the efficacy of antiviral therapy for chronic hepatitis B. It has recently been documented that antiviral therapy may decrease the HCC risk in chronic hepatitis B patients with normal to minimally elevated ALT and no cirrhosis (Hoang et al. 2016). Risk calculators for many other environmental diseases may also be developed if there were good large-scale long-term cohort studies on the diseases.

Promotion of global health through environmental health intervention

With increasing globalization, environmental pollution, or infectious disease outbreaks in one country may result in environmental disasters and health hazards in both adjacent and remote countries. Public health can be promoted through environmental health interventions including the prevention of air, water, and soil pollution with chemicals or biological agents; the reduction in exposures to ultraviolet, ionizing radiation, noise, and electromagnetic fields; improvement of built environments including housing, land use patterns, and roads; minimization of carbon dioxide emission, combating global warming leading to severe climate change, and ecosystem deterioration; optimization of agricultural methods and irrigation schemes; and promotion of occupational safety and security, and so forth.

Many environmental health interventions are more cost-effective compared with other kinds of health-sector efforts. These interventions often yield long-term benefits in addition to immediate health improvements. Reduction in the burden of environmental diseases may help the eradication of extreme poverty and hunger, the reduction in child mortality, the improvement in maternal health, the maintenance of environmental sustainability, and the control of epidemics including AIDS/HIV, malaria, tuberculosis, and other infectious diseases. Global partnerships need to be strengthened to achieve interrelated goals of health, environmental sustainability, and development.

7.2

Radiation and public health

Leeka Kheifets, Adele Green, and Richard Wakeford

Introduction to radiation and public health

The electromagnetic spectrum encompasses frequencies that range from above approximately 10^{20} hertz (Hz) for ionizing radiation at the high end of the spectrum to static fields and power frequencies of 50–60 Hz at the low end. In order of decreasing frequency, the spectrum comprises gamma-rays, X-rays, ultraviolet radiation, visible light, infrared radiation, microwaves, radio waves and extremely low frequency electric and magnetic fields (ELF EMF) (Fig. 7.2.1). This chapter reviews sources and health effects of human exposure to radiation within the electromagnetic spectrum, and for ionizing radiation exposure to subatomic particles, and reviews policies for limiting human exposure where appropriate.

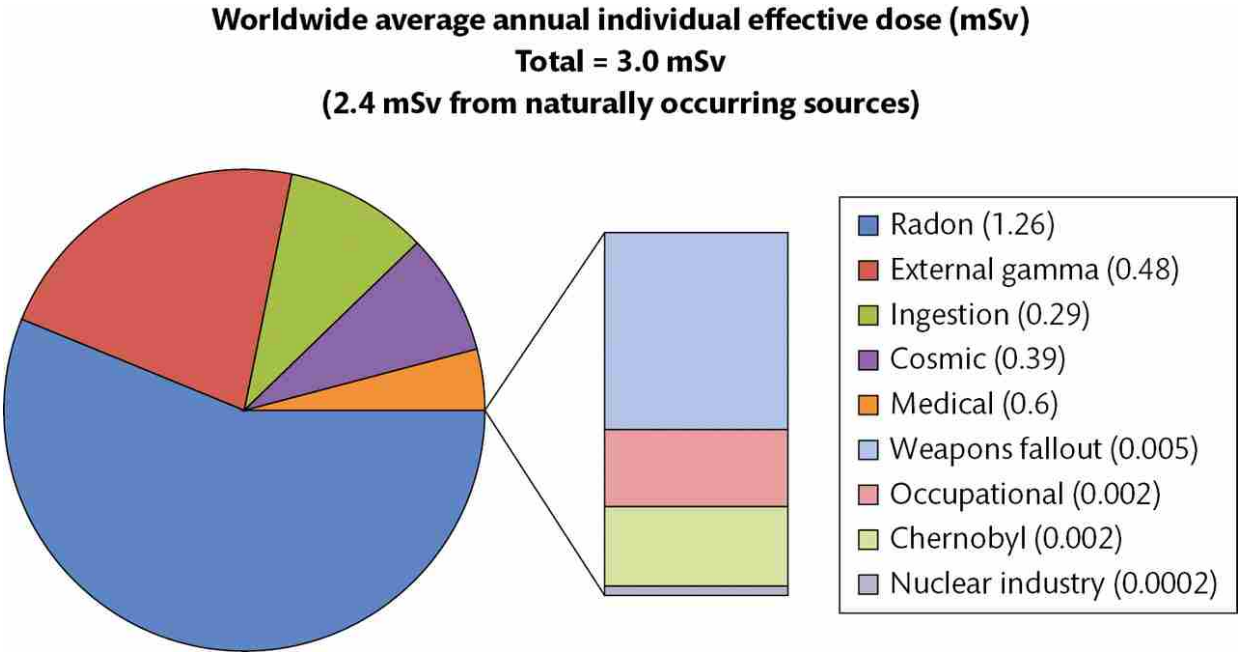

Fig. 7.2.1 Major sources and electromagnetic spectrum.

The focus of research and our knowledge of the health effects of these forms of energy have been driven, at least partly, by episodes of exposure of the general public (e.g. for ionizing radiation, the extensive studies of the Japanese survivors of the atomic-bombings of Hiroshima and Nagasaki), although valuable additional information has been derived from studies of occupational and medical exposures. Our understanding varies: for ionizing radiation, ultraviolet radiation, and extremely low frequency fields (ELF), numerous state-of-the art epidemiologic and toxicologic investigations encompassing a variety of endpoints have been undertaken; a lot of the recent research has been on radiofrequency fields (RF), but focused on m mobile phone use and tumours of the head and neck, with less attention to other sources and outcomes. Although numerous studies of static fields have been completed, here too, much of the key research is yet to be done; for infrared radiation and intermediate frequencies only scant information is available. Technological developments involving exposure to electromagnetic fields bring social and economic benefits to large sections of society but the health consequences can be difficult to predict and manage. As countries increase their capacity to generate and distribute electricity and take advantage of the many new technologies—such as telecommunications—to improve lifestyle and work efficiency, exposures to electric and magnetic fields from 0 to 300 GHz (non-ionizing radiation) has been

increasing rapidly. Further, the use of ionizing radiation in medicine, such as computed tomography (CT) scanning and nuclear medicine, has led to increases in exposure, particularly in economically developed countries. In this chapter, our main emphasis is on exposures common in everyday life rather than occupational exposures. When relevant, we also consider separately exposures from medical applications, as these exposures are commonly higher, but carry a different risk/benefit ratio for exposed individuals.

Static fields

Sources and environmental levels (static fields)

For a steady current in a circuit corresponding to zero-frequency (static fields), the charge density at any point of the circuit is constant, and therefore, the electric fields are constant in time. Since magnetic fields are created by moving electric charges, magnetic fields are also constant for static fields. The unit of measurement for magnetic fields is tesla (T). Another commonly used unit in engineering sciences is gauss (G); one T is equivalent to 10,000 G. Environmental exposure levels are described in microtesla (μT), or 10^{-6} T.

There is a natural static magnetic field that originates from the electric current flowing in the upper layer of the Earth's core, as well as solar activity and atmospheric processes. There are significant local differences in the strength of this field: the vertical component of the field reaches a maximum of about 70 μT at the magnetic poles, and approaches zero at the magnetic equator; conversely the horizontal component is close to zero at the poles and is a maximum of just over 30 μT at the magnetic equator.

In addition to the Earth's magnetic field are man-made magnetic fields of significantly higher strength. Major sources of exposure to the general public are transportation and magnetic resonance imaging (MRI). In general, electrified railway systems produce some of the largest static field levels encountered by the general public. Static fields up to several tens of microtesla have been reported inside trams operating on direct current (European Commission 1996). Modern magnetic levitation (maglev) systems use very high fields (around 1 T) directly on the rails; inside the trains fields vary between 50 μT and 10 mT depending on the cabin design.

MRI systems have proliferated in recent years and there are currently many thousands worldwide. The static magnetic fields are in the range of 0.2–3 T for systems for routine clinical use. MRI also utilizes much smaller time-varying gradient magnetic fields and radio frequency radiation. Medical applications use fields from 1.5 to 10 T (Gowland 2005). Sources of exposure that are either relatively uncommon or small include steel construction materials, high voltage DC transmission lines, headphones and telephone speakers, and steel-belted radial tires. Use of magnetic plasters, blankets, and mattresses for therapeutic properties have surface magnetic flux densities of about 50 mT but decay quickly within a few millimetres and are not used widely (European Commission 1996). High occupational exposures to static fields are encountered in several industrial processes including aluminium and chlorine production, gas welding, and in accelerator research.

Health effects (static fields)

The three established biophysical mechanisms are magnetic induction, and magneto-mechanical and electronic interactions. Laboratory studies of animals show aversive responses and field avoidance at 4 T or higher, probably vestibular in nature. Thresholds for motion-induced vertigo are estimated to be 1 T per second for greater than 1 second.

Cancer (static fields)

The few epidemiological studies published to date leave a number of issues unresolved concerning the possibility of increased cancer risk from exposure to static magnetic fields. These studies have been carried out almost exclusively on workers exposed to static magnetic fields generated by equipment using large direct currents (DC). Assessment of exposure has been poor, and the number of participants in the studies has been very small. Most of the studies were conducted in aluminium or other smelter plants. These studies are limited in their ability to provide useful information: in fact they do not provide clear evidence for increased risk due to more established, carcinogens present in some of these work environments: aluminium reduction creates coal tar, pitch volatiles, fluoride fumes, sulphur oxides, and carbon dioxide. Although some welders are exposed to relatively high static fields in some processes, they are also exposed to fumes and ELF

and RF magnetic fields. Furthermore, most of the studies on welders do not provide enough information to determine the type of welding used, limiting the usefulness of these data in assessing potential health effects of static magnetic field exposure. Other work environments with a potential for high fields, for example as experienced by MRI technicians, have not been adequately evaluated, but have been identified as a high research priority by the World Health Organization (World Health Organization [WHO] 2006). In short: there is insufficient information for proper risk assessment of the impacts of static magnetic fields on cancer. Evidence from animal carcinogenesis studies is inconclusive, in the few studies that have been carried out (van Rongen et al. 2007).

Other outcomes (static fields)

Even less information is available on other outcomes such as reproductive outcomes. One study examined fertility and pregnancy outcomes in female MRI operators, where the potential for exposure to relatively large static fields of up to ~1 T may have existed. The risk of miscarriage for pregnancies during MRI work was slightly increased compared to work in other jobs and was considerably higher than the risk of homemakers (Evans et al. 1993), but the study was methodologically weak. No adverse effects have been demonstrated in animal studies, but there are few good studies, especially with exposures in excess of 1 T (WHO 2006). A priority for further research is to investigate any potential harmful effects from exposure to the foetus during pregnancy, particularly during the first trimester.

Policy and prevention (static fields)

Exposure to equipment generating large static electric fields is uncommon. Exposures to large static magnetic fields (up to several tens of mT) occur as a result of the industrial use of DC electric currents, for example in welding and electrolytic processes, and less commonly in high energy physics laboratories and experimental fusion reactors. Few countries have developed exposure guidance.

However, exposure may be becoming more common. With the advent of superconductor technology in the latter part of the twentieth century, it has been possible to develop large electromagnets capable of generating fields in excess of 1 T. Patient exposure to fields of 1–3 T during clinical MRI

diagnostic procedures is now routine, and up to 10 T is becoming more common. MRI is increasingly used in paediatric diagnostic imaging, and a cohort study into the effects of MRI exposure on children is recommended as a high priority by the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) (2015). Additionally, a priority for further research is to investigate any potential harmful effects from MRI exposure to the foetus during pregnancy, particularly during the first trimester (ICNIRP 2009). Most MRI use involves relatively short scans of less than 1 hour, and there are usually clear benefits to the person being scanned, hence the approach to guidance on exposure is different from that adopted for occupational and public exposure, because of the different risk/benefit ratio to those concerned.

The International Commission on Non-Ionizing Radiation Protection (ICNIRP) (2009) recommended a spatial peak magnetic field of 2 T for head and trunk, which can be raised to 8 T for limbs or in a controlled environment. For the general public, it is recommended that an exposure should not exceed 400 mT. Special consideration should be given to patients: their whole-body exposure should be limited to 4 T in normal mode, and go up to 8 T in a controlled mode. More caution is recommended above 8 T, which is considered experimental and should be accompanied by clinical monitoring. Further, to avoid vertigo and nausea, patients should move or be moved slowly during the MRI procedures and in the presence of high fields.

Extremely low frequency fields

Sources and environmental levels (ELF)

Extremely low frequency electromagnetic fields (ELF EMF) are associated with all aspects of the production, transmission, and use of electricity. The fields are imperceptible to humans and are ubiquitously present in modern societies. ELF EMF are composed of two separate components, electric fields and magnetic fields. Electric fields are created by electric charges and are measured in volts/metre (V/m). Typical residential exposure levels are under 10 V/m. In the immediate vicinity of electric appliances, exposure levels can reach as high as several hundred V/m, whereas exposure levels immediately under high-tension power lines can reach several thousand V/m.

Average magnetic field exposures in the workplace have been found to be higher in electrical occupations which include power and telephone line workers, electricians, and electrical engineers, among others, than in other occupations such as office workers. Exposures range from 0.4 to 0.6 μT for electricians and electrical engineers, to approximately 1.0 μT for power line workers and above 3 μT for welders, railway engine drivers, and textile workers. By contrast, typical residential exposure levels are around 0.1 μT. In the immediate vicinity of electric appliances that are in use, magnetic fields could be as high as several hundred μT but are usually only of short duration.

Health effects (ELF)

Since the late 1970s, numerous epidemiologic studies of varying quality have investigated possible health risks from residential and occupational exposure to both electric and magnetic fields.

Cancer (ELF)

An association between higher-than-average magnetic field exposure levels and leukaemia risk is reported in most of almost 40 epidemiologic studies investigating childhood leukaemia and ELF EMF. However, most of them are based on a small number of highly exposed cases and thus lacked precision. A robust biologic hypothesis to explain this association is lacking. In 2000, two independently conducted pooled analyses of previously published studies showed a statistically significant, approximately twofold increase in childhood leukaemia risk for average residential exposure levels above 0.3 or 0.4 μT, compared to the lowest exposure category of ≤ 0.1 μT (Ahlbom et al. 2000; Greenland et al. 2000). More recently, Kheifets et al. (2010a) identified 14 studies published since the two previous 2000 pooled analyses, of which seven met their inclusion criteria. The odds ratios for exposure above 0.3 μT compared to <0.1 μT was 1.44 (95% confidence interval (CI): 0.88–2.36). Without the most influential study from Brazil, which is suspected to be particularly prone to bias, the odds ratios increased and became similar to previous pooled analyses. Risk increases this small are notoriously hard to evaluate in epidemiology because it is usually difficult to achieve enough precision to distinguish a small risk from no risk. Such small effect estimates, compared to larger ones, are also more likely to

result from inadvertent error, or bias, that can occur in epidemiologic studies (Greenland and Kheifets 2006). Selection bias, which can arise in the process used to select or enrol study participants, might explain some of the observed association (Mezei and Kheifets 2006). Given (1) the small associations observed in studies of magnetic fields and childhood leukaemia; (2) a limited understanding of causal risk factors for childhood leukaemia; (3) methodological difficulties in an assessment of a non-memorable and highly variable exposure; and (4) the potential for selection bias, a conclusive interpretation of these findings remains a challenge. The lack of a robust biophysical mechanism that would explain how environmental magnetic fields could cause cancer and a lack of support from laboratory investigations also indicates that the findings might be a result of study design and measurement issues rather than being truly causal. However, the remarkable consistency of epidemiologic studies is difficult to dismiss, or entirely explain.

Kheifets et al. (2010b) performed a similar pooled analysis for childhood brain tumours. In contrast to childhood leukaemia, there was little indication of an elevation in risk in the highest exposure category, and much less of a monotonic exposure-response relationship (with risk ratios below one in intermediate exposure categories). Results for other cancers, such as adult leukaemia and brain cancer (occupational exposures mostly) are less consistent than those for childhood leukaemia (Kheifets et al. 2008). For breast cancer a biologic mechanism has been proposed but has not been confirmed in recent epidemiologic studies which strongly argue against an association (WHO 2007).

Other health outcomes (ELF)

A number of additional health outcomes, particularly neurodegenerative disease, cardiovascular disease, and reproductive outcomes have been investigated in epidemiologic studies.

Few EMF studies on multiple sclerosis and epilepsy exist to evaluate the evidence. There is no evidence linking EMF and Parkinson’s Disease and only very weak evidence to suggest that they affect Alzheimer’s disease. The evidence that people employed in electrical occupations have an increased risk of developing Amyotrophic lateral sclerosis (ALS) substantial, perhaps because such employees have an increased risk of experiencing an electric shock rather than any long-term exposure to the fields *per se* (Vergara et al.

2013). The epidemiologic results are thus inconsistent and lack supportive laboratory evidence.

There is some evidence for increased miscarriage risk associated with high residential EMF exposure, however methodologic problems make interpretation of these studies difficult (Lewis et al. 2016). In particular, there are: difficulties in studying EMF exposure levels similar to background levels, capturing early miscarriages, and reporting accurate information free from recall bias. There is little evidence of increased risks of adverse reproductive outcomes other than miscarriage, although good data are lacking (WHO 2007). The results of the studies on paternal ELF EMF exposure and adverse reproductive outcomes are unconvincing.

Epidemiologic investigation of cardiovascular diseases has been motivated by biologically based hypotheses which stemmed from two independent lines of evidence: (1) magnetic fields were reported to reduce the normal heart rate variability in human experiments, and (2) several prospective cohort studies have suggested that reductions in some components of heart rate variability are associated with increased risk for heart disease, overall mortality rate in survivors of myocardial infarction, and sudden cardiovascular death. Thus, it was hypothesized that occupational exposure to magnetic fields increases the risk for cardiac arrhythmia-related conditions and acute myocardial infarction, but not chronic cardiovascular disease. Although an initial study appeared to support this hypothesis, recent larger and more rigorous studies have found no effects and have failed to confirm earlier findings and suggest that ELF magnetic fields do not play a role in the development of cardiovascular diseases (Kheifets et al. 2007).

Policy and prevention (ELF)

During the past decade, a number of national and international expert panels, including ones assembled by the United States National Institute of Environmental Health Sciences (NIEHS) (1999), the International Agency for Research on Cancer (IARC) (2002) and the WHO (2007), have reviewed the evidence on the potential relationship between exposure to ELF EMF and various adverse health outcomes. Evaluations by these expert panels generally agree that short-term, adverse effects do not occur at exposures to magnetic fields below 100 μT. Current guidelines (recently revised) are

based on induced internal electric fields and use a threshold for an induction of magnetic phosphenes. For general public exposure, the reference levels for power frequency (50 Hz) electric and magnetic fields are of the order of 5 kV/m and 200 μT, respectively. These values are well above levels encountered in most environments.

Based on these intensive reviews IARC and WHO classified ELF magnetic (but not electric) fields as a 'possible human carcinogen', or a Group 2B carcinogen. This classification was based both on epidemiologic evidence showing a consistent association between exposure to ELF magnetic fields and childhood leukaemia even though laboratory studies in animals and cells, do not support an association between exposure to ELF magnetic fields and cancer.

Several risk characterization attempts have indicated that the public health impact of residential magnetic fields on childhood leukaemia is likely to be limited (Kheifets et al. 2006). The combination of widespread exposures, established biological effects from acute, high-level exposures, and the possibility of leukaemia in children from low-level, chronic exposures have made it necessary but difficult to develop consistent public health policies. In view of these uncertainties, it might be advisable to adopt general no- and low-cost measures to reduce exposure (WHO 2007). The choice of precautionary measures can be informed by a health-economics analysis conducted so far only in a few countries (Kandel et al. 2016).

Intermediate frequency

Intermediate frequency (IF) exposures occur in the range 300 Hz to 10 MHz, partially encompassing frequencies also assigned to very low frequency (VLF; 0.3–30 kHz) and high (3–30 MHz) ranges.

Because few biological studies of exposures to intermediate frequencies have been conducted, exposure guidelines have largely been extrapolated from the encompassing ELF (at the low end) and RF (at the high end) limits.

Sources and environmental levels (IF)

IF exposures from occupational appliances (e.g. induction heaters for heating metals prior to manipulation and plasma heaters) are common. Smaller exposures occur from induction heating elements in residential

cooking appliances. Television, radio, and other communications transmitters can emit IF, but they are discussed in the section on RF, which constitutes the much more common wavelengths of exposure from such sources. Indirect exposures from medical equipment (e.g. MRI machines and magnetic bone stimulators where pulses may drop to IF levels) may occur rarely. Direct exposures to IF may also occur from surgical equipment used for tissue cutting and cauterizing. Common exposures to IF occur in proximity to devices that read magnetic cards or buttons for identification purposes (Polichetti and Vacchia 1998), and similarly, from antitheft devices that read magnetic identification tags. Very small exposures are obtained from television screens (and old computer monitors). Use of antitheft technologies, device tagging, and identification is increasing rapidly, exposures immediately beside radio-frequency identification (RFID) reader antennae can be locally higher, and simultaneous exposures can come from a variety of IF sources, locations of which may be unknown (ICNIRP 2008).

Health effects (IF)

Since exposure level and proximity to the source together determine the IF levels in tissue, knowledge of both is important in determining the biological effects of IF exposure levels in humans. Effects can be either thermal, when frequency is sufficient to induce a heating response, or non-thermal (i.e. cell membrane excitation or electroporation), when frequency does not induce a heating response. Studies of the impact of IF on human health, particularly with exposure from new technologies, are currently lacking.

Policy and prevention (IF)

Because of the lack of data, currently there are no specific recommendations for limiting exposure to IF, other than those extrapolated from EMF at extremes of the IF range (ELF and RF). As use of IF fields and subsequent exposure to the population is increasing, there is an increased interest in characterizing exposure and health effects in the IF range (Generalised EMF Research using Novel Methods [GERoNiMO] n.d.).

Radiofrequency radiation

Sources and environmental levels (RF)

With rapid advances in EMF technologies and communications, people are increasingly exposed to frequencies in the radiofrequency (RF) range. RF fields are produced by radio and TV broadcasts, mobile phone base stations, and other communication infrastructure. The most relevant exposure is to mobile phones. This technology typically uses frequencies from 450 to 2,500 MHz, although new technology has broadened this band to GHz range.

Other sources of exposure to the general population are radio and television transmitters which operate at between 200 kHz and 900 MHz. Radio and TV signals are broadcast to a large area from comparatively few sites (Neubauer et al. 2007). Compared to radio and TV transmitters, mobile phone base stations cover a smaller area, and produce much lower emissions, but are vastly more common in many countries. Residential exposures also come from wireless monitors used in children's cribs, cordless phones, and Wi-Fi (wireless Internet connections) commonly used at home and in schools. Occupational exposures include RF PVC welding machines, plasma etchers, and military and civil radar systems. All operate at different frequencies.

Handheld mobile phones available since the late 1980s became widely used by the general population only in the late 1990s. Currently there are more than 5 billion mobile phone users worldwide, with a penetration in some countries reaching 120% (i.e. many people have more than one). Use of mobile phones has changed markedly over recent years, concomitant with the development of new technologies (e.g. 2G to 3G, power control, handover management, and novel uses of smartphones). Phones operating under 2G and 3G can have significantly different output power; 3G is thought to be around 1% of the power emitted by a phone operating under 2G. 5G technologies and networks use the largely untapped bandwidth of the millimetre wavelength, between 30 and 300 GHz on the radio spectrum, which uses smaller base stations than current wireless technology. As a result, wireless antennae may be placed densely throughout neighbourhoods on infrastructure such as lamp posts, utility poles, and buildings. The Internet of Things (IoT) and machine-to-machine (M2M) devices are also becoming a reality.

In addition, modes of mobile phone use are constantly changing as texting, web-surfing, playing games, and listening to music and video streaming on mobile phones are now common. Exposure from mobile

phones is concentrated closest to the handset and the antenna. Absorption of RF from mobiles is localized and depends on the position of the phone during use. This represents a very important determinant of exposure: only calls made with the mobile phone close to the head result in absorption of RF energy inside the head.

For whole-body exposure, mobile phone base stations can be the largest individual source of RF, but other sources such as radio or TV transmitters can result in comparable exposures depending on where the measurements are taken. For RF sources other than mobile phones, typical power densities outdoors would be 0.01–1 mW/m^2, but could be orders of magnitude higher (i.e. 100 mW/m^2 and above). Indoor levels are often lower than outdoor exposures by orders of magnitude; for example, in Europe, a median indoor power density of 0.005 mW m^{-2} has been reported. Recent study of European children reports median total personal RF-EMF exposure of 75.5 $\mu W/m^2$ (Birks et al. 2018). Downlink was the largest contributor to total exposure (median: 27.2 $\mu W/m^2$) followed by broadcast (9.9 W/m^2). Exposure from uplink (4.7 $\mu W/m^2$) was lower. Wi-Fi and digital enhanced cordless telecommunications (DECT) contributed very little to exposure levels in children. While exposures from mobile phone base stations are several orders of magnitude lower than from phones, it differs from that of mobile phones in other ways: base stations expose the whole body, and the exposure duration is considerably longer. Perhaps more importantly, base station exposure has been a subject of much concern to the public because it is not under the control of the public and its presence is not perceived to be of direct individual benefit.

Population exposures to RF fields are less completely characterized than exposures to ELF fields. This is due to: (1) technical challenges; (2) the rapid evolution of RF-related technology (frequency, coding schemes); and (3) changing patterns of use (duration of calls, text messaging, web-surfing, etc.).

Health effects (RF)

Since RF radiation induces heating in body tissues and imposes a heat load on the whole body, prevention of excessive heating serves as a basis for most international guidelines for human exposure. Studies of the interaction of RF with tissue in the range used for mobile phones have led to the proposal of

many different non-thermal mechanisms for RF interaction. Generally, it is thought that non-thermal interactions are unlikely to be biologically significant at the RF levels below guidance values, but much of the on-going research is directed towards non-thermal mechanisms.

Cancer (RF)

Epidemiological studies of health effects related to RF exposure from mobile phones are numerous and have primarily focused on cancer, especially brain tumours, although studies with long-term exposure with sufficient latency are still limited. Currently it is only possible to evaluate short- to medium-term effects of mobile phone exposure; while some studies report effects for heavy or long-term users (Coureau et al. 2014), the majority of studies have found no effects on either brain or parotid gland tumour risk (Swerdlow et al. 2011). Exposure assessment remains problematic: substantial random error has been shown for even short-term recall of mobile phone use; and information bias appears to affect at least the reporting of the side of the head where the phone is commonly used. Also, some studies may be compromised by a non-representative control group, caused by an increased participation of mobile phone users. Results for acoustic neuroma are more suggestive albeit inconsistent (Swerdlow et al. 2011). Recently, a few studies have examined other cancers, such as leukaemia, non-Hodgkin's lymphoma, and uveal and testicular cancers. Results are unremarkable, but subject to the same limitations as brain tumour studies. So far only one study has examined the possible association between brain tumours and use of mobile phones in children (Aydin et al. 2012). Small and imprecise risks were reported in the high exposure categories, which became more pronounced in a subgroup of about one-third of the subjects for whom objective operator data were available. However, due to methodologic limitations, some internal inconsistencies, and most importantly, lack of increases in the brain tumour rates for children in the registry, the authors considered their data to argue against causality. Clearly, more studies of children are needed.

A few studies have assessed cancer risk in relation to radio and TV transmitters (Ahlbom et al. 2004). Often driven by a previously identified cancer cluster, these analyses are based simply on distance from the source and often include an extremely small number of cases. It is therefore not surprising that such studies have been uninformative. Four recent case–control studies of cancer risk related to mobile phone base stations (Ha et al.

2007; Merzenich et al. 2008; Elliott et al. 2010; Li et al. 2012) have employed improved methods both in terms of design and exposure assessment. While reporting some positive associations for disease and exposure subgroups, overall these studies provide no consistent evidence of association between exposure from base stations and other transmitters and risk of childhood cancer. However, numerous methodologic limitations remain, including the inability to detect small increases in risk.

Although occupational studies have been performed over a longer time period, we are only beginning to measure and learn about RF exposures in various occupations, and the exposure may not always be relevant for an assessment of effects of mobile phone frequencies. Although some increased risks have been found in certain studies, there is no consistent evidence of risk increases for any cancer sites. The studies have several methodological weaknesses: (1) studies are not based on measurements of the actual RF exposure for the subjects included; (2) exposure classification has often been based on job title alone; and (3) control of confounding, if any, has been limited (Ahlbom et al. 2004).

All of the studies have reported null results for carcinogenicity in normal animals at exposure levels compatible with mobile phones, however, co-carcinogenicity studies have been suggestive (IARC 2012). As a result, IARC classified RF as possibly carcinogenic to humans based on limited evidence in humans (from studies of glioma and acoustic neuroma in relation to mobile phones) and limited evidence in animals (based on co-carcinogenicity studies). Of note is the most comprehensive animal study conducted by NIEHS investigating whether mobile phone radiation increases cancer risk in rats and mice. The NIEHS study has not yet been published in peer-reviewed literature, but has been reviewed extensively by a panel of outside reviewers (National Toxicology Program 2018). The panel concluded that for most frequencies/modulations/species the evidence of carcinogenic activity was equivocal, while for several combinations of frequencies/modulations/species some evidence of carcinogenic activity was found, raising to clear evidence of carcinogenic activity for male rats based on incidences of malignant schwannoma in the heart and code-division multiple access (CDMA)-modulated mobile phone radio frequency radiation (RFR) exposure at 900 MHz. In addition, while GSM- or CDMA-modulated cell phone RFR at 1,900 MHz did not increase the incidence of any non-neoplastic lesions in male or female mice, increases in non-neoplastic

lesions in several organs in both males and females exposed to GSM and CDMA cell phone RFR at 900 MHz was reported. The final interpretation must await the report and peer- reviewed publications, which are expected in the latter part of 2018.

Other outcomes (RF)

It is well established in animal studies that hyperthermia during pregnancy can cause embryonic death, abortion, growth retardation, and developmental defects; development of the central nervous system is especially susceptible. Numerous studies have evaluated developmental effects of RF fields on mammals, birds, and other non-mammalian species (Heynick and Merritt 2003; Independent Advisory Group on Non-Ionizing Radiation 2003). These studies have shown that RF fields are teratogenic at exposure levels that are high enough to cause significant increases in temperature. There is no consistent evidence of effects at non-thermal exposure levels, although a few studies have evaluated possible effects on postnatal development using sensitive endpoints, such as behavioural effects. Serious health effects of hyperthermia in humans, however, are associated only with greatly elevated body temperatures (>40°C), and such temperature rises are well above those generated by the maximum allowable level for public RF exposure.

Several studies of occupational RF exposure, primarily in physiotherapists, have reported an increased risk of congenital malformations, but no specific type of malformation has been consistently reported, and there is a potential for recall bias in these studies (Larsen 1991). Exposure to RF during sensitive periods of development in early life may lead to lasting effects on health (Kheifets et al. 2005). No association was found between mobile phone use during pregnancy and early neurodevelopment in very young children in two studies (Vrijheid et al. 2010; Divan et al. 2011). A Danish study has raised the hypothesis that pregnancy and childhood exposure to mobile phones may result in common childhood behavioural problems (Divan et al. 2008). Prospective evaluations of this association were confirmed in the same cohort (Sudan et al. 2016). Behavioural problems related to mobile phone use in children stands out as the only association independently confirmed in several studies (Abramson et al. 2009; Divan et al. 2012; Thomas et al. 2010), including in pooling of individual participant data from five cohorts found that maternal mobile phone use during pregnancy may be associated with an increased risk for

behavioural problems, particularly hyperactivity/inattention problems, in the offspring (Birks et al. 2017).

Possible health effects based in part on anecdotal reports of numerous symptoms such as headaches and sleep disturbance from continuous whole-body RF exposure from base stations is an area of major public concern. Because of numerous methodologic shortcomings, data regarding effects of such RF exposure on symptoms are inadequate for assessment at present.

Policy and prevention (RF)

Guidance on exposure for the general public is intended to restrict local tissue temperature rises to acceptable levels and currently is set to 0.08 Wkg^{-1}, for the whole body, and 2 Wkg^{-1}, for the head. Mobile phones have only been in widespread use for a relatively short time and therefore, the possibility remains that long-term RF exposures from mobile telephony can have adverse health effects. More importantly, many of the health outcomes are yet to be studied and research on potential detrimental effects on children is particularly sparse.

The need for public health policy coupled with the paucity of data, particularly for children regarding the long-term health effects of mobile phone use, suggests that low-cost precautionary measures are appropriate. Mobile phone use is increasingly common among school children, and teenagers may be among the heaviest mobile phone users today with some exposures close to guideline limits (Kheifets et al. 2010c). Exposure can be reduced by users restricting the length of their calls, or by using ‘hands-free’ devices to keep mobile phones away from the head and body.

Infrared radiation

Sources and environmental levels (IR)

Wavelengths between 780 nm and 1 mm are classified as infrared radiation (IR). The IR spectrum is conventionally broken down into three separate categories: IR ‘A’ (780 nm –1.4 μm); IR ‘B’ (1.4–3 μm); and far-IR ‘C’ (3 μm–1 mm). Besides solar radiation and fire as common natural sources, artificial sources of IR include a variety of therapeutic and domestic applications such as heating devices, lights, ‘infrared saunas’, and industrial

sources related to heat production such as in steel/iron industries. Lasers comprise a special group that emits IR radiation over one or more extremely narrow wavelength bands, not covered in detail here.

Health effects (IR)

IR penetrates human skin and ocular tissues, namely the cornea, lens, and retina, to varying depths depending on wavelength and tissue type. For example, far-IR can penetrate to almost 4 cm beneath the skin surface (Vatansever and Hamblin 2012). Humans have protective aversion responses to thermal pain and to the bright light/visible radiation that is often also present, so that potentially hazardous exposure can be avoided. When harmful effects of IR in humans do occur, most studies suggest that the main mechanism of action is thermal injury, with little evidence of photochemical or other biological interactions. The principal chromophore of far-IR wavelengths is water and when far-IR is used therapeutically (see next), it is again believed to be mostly by thermal mechanisms causing for example increased nitric oxide production with beneficial effects on vascular endothelial function, but there may also be other less understood biological effects at energy levels too low to cause heating (Vatansever and Hamblin 2012; Shui et al. 2015).

Harmful effects (IR)

Harmful effects of any episode of hyperthermia of the skin depend on the intensity and the duration of the IR exposure (Moritz and Henriques 1947). When the temperature of the skin is held at 44°C, around 6 hours is required before irreversible skin damage is sustained, while at surface temperatures of 70°C or higher, less than 1 second is required to cause epidermal necrosis (Moritz and Henriques 1947). In industrial settings, whole-body heat stress tends to limit the duration of exposure to IR radiation, keeping it under the threshold for thermal damage to the skin, and so, only very brief exposures to very high irradiances pose a thermal hazard. Chronic IR exposure of the skin without burning (such as repeatedly sitting with exposed skin close to open fires—common in the past) can cause a distinctive red-brown mottling of the skin known as erythema ab igne. IR is not considered relevant in the initiation of skin cancer although it has been hypothesized that IR might

accelerate UV-induced skin carcinogenesis (Edwards et al. 1999), possibly by reducing DNA repair ability (Dewhirst et al. 2003), or by triggering damage by reactive oxygen species, but supportive evidence is scant.

The main detrimental effect of high IR exposure is to the eye due to the sensitivity of the cornea, iris, lens, and retina to thermal damage, though damage thresholds for these tissues vary greatly depending on the precise wavelength and exposure duration. For example, with laser irradiation at 1.315 μm, the cornea is the most sensitive of the tissues to continuous wave exposure. The retina, lens, and iris are sensitive to short exposure durations of ~0.1–1.0 seconds, and the retina is the eye tissue most sensitive to damage by submillisecond laser pulses (Zuclich et al. 2007). When incident IR radiation is absorbed by the cornea it is converted into heat which is conducted to the lens with marked decreases in lens proteins whose aggregation is thought to lead to the lens opacity of cataract (Aly and Mohamed 2011). There is considerable evidence of IR-induced cataract in industries with extremely high exposures, e.g. glass workers (Lydahl and Philipson 1984) and iron and steel workers (Wallace et al. 1971). Most non-industrial exposures to IR appear insufficient to cause cataract or other eye damage, however.

Workers exposed to high levels of IR contend with whole-body hyperthermic effects (rise in body temperature causing heat stress) which are similar to those in any industry involving physical activity in warm environments. The same is likely true of risks of excessive exposure to far-IR saunas or warming cabins. Thus, the exposure limits in these situations will rely mainly on ensuring that safe body temperatures are maintained.

In summary, there have been relatively few studies of the health effects of IR, but current evidence suggests that harmful effects are few and due to acute high intensity exposure or to chronic exposure, causing ocular damage and heat-related illness in certain situations.

Beneficial effects (IR)

Far-IR (around 10 μm wavelength) saunas operate at lower temperatures than traditional saunas and promote greater sweating since skin penetration by IR is greater than by hot air. Their use is widely believed to bring general salubrious effects as well as improved health in patients with cardiovascular disease, diabetes mellitus, and chronic kidney disease though supportive

evidence from randomized controlled trials, non-randomized trials and cohort studies is limited (Beever 2009). Other therapeutic applications include far-IR ray devices used for a range of conditions, from allergic rhinitis to arteriovenous fistula malfunction in haemodialysis patients, and far-IR-emitting ceramics and fabrics that are worn for example for relief of pain (e.g. arthritis, dysmenorrhoea) (Vatansever and Hamblin 2012).

Policy and prevention (IR)

There are various international standards for limiting exposure to IR that are provided separately for IR-A, B, and sometimes C (ICNIRP 2006). These limits, based on combinations of wavelength and time of exposure, are most appropriate for industrial applications where exposures are extreme and measurable. The heat-generating effects of IR tend to be avoided when humans react to minimize their exposure before thermal injury to the skin occurs. This is not true for exposures causing cataract, so specific recommendations exist for wearing protective eye coverings and limiting exposure to IR. Again this applies largely to occupational settings with extreme exposures and assumes that any exposure of the eye to IR is potentially harmful.

There are currently no recommendations for limiting or avoiding exposures to IR in saunas and other recreational settings other than to limit exposure to avoid heat-related illness.

Ultraviolet radiation

Sources and environmental levels (UV)

Ultraviolet (UV) radiation is categorized as UVA (400–320 nm), UVB (320–280 nm), and UVC (280–250 nm), and the sun is the natural source. All UVC and much of the UVB emitted by the sun are absorbed by the Earth's atmosphere such that the midday sun comprises about 95% UVA and 5% UVB. Although in recent decades depletion of ozone in the stratosphere by man-made chlorofluorocarbons has resulted in greater levels of UVB on the Earth's surface in some temperate and arctic regions. Solar UVB levels increase with decreasing latitude and increasing altitude and are highest in the summer and in the middle hours of the day; levels of ambient UVA

mostly parallel UVB levels. Light cloud cover prevents about 50% of solar UV energy from reaching the Earth's surface, while very heavy cloud cover can virtually eliminate UV radiation (Diffey 1991). Reflectance from light-coloured surfaces such as concrete, snow, and to a lesser degree, water, increases terrestrial UVB.

There are many sources of artificial UV found in occupational and medical settings and these include mercury vapour lamps, arc-welding, commercial germicidal UV lamps, and dental polymerizing equipment. In addition, over the last two decades the sunbed industry has emerged as a prevalent source of community UV exposure, sought after by fair-skinned people, particularly adolescents and young adults, seeking to acquire a tan by artificial means (Olsen and Green 2012).

Health effects (UV)

The penetration of human tissues by UV radiation and the ensuing health effects are not only wavelength-dependent with longer UVA wavelengths penetrating human tissues more deeply than UVB, but also age-dependent. The structure of juvenile skin and eyes may result in increased UV dosage and damage to target cells compared with adults resulting in childhood susceptibility to later, long-term degenerative or carcinogenic effects (Green et al. 2011a). For example, in the juvenile eye, the crystalline lens allows UV transmission to the retina and choroid, whereas after around 25 years of age the adult lens and cornea filter almost all UV (Lerman 1984).

Harmful effects (UV)

Acute exposure to UVB causes inflammation of the skin (sunburn) and eye (photokeratitis of the cornea) and immunosuppression (Young 2006). Chronic UV exposure of the skin causes photoaging, benign keratinocytic skin tumours (actinic keratoses), and skin cancer (basal cell and squamous cell carcinomas (BCC and SCC) and melanoma) (IARC 2012). Skin colour determines sensitivity to the acute and chronic effects of UV radiation on the skin, with white Caucasians bearing most of the burden of harmful effects compared with those with black or olive skin. Chronic UV exposure of the eye causes a range of degenerative effects, e.g. pterygium, cataract, macular

degeneration, as well as cancer (SCC and ocular melanoma) regardless of skin and eye colour.

The carcinogenic effects of solar UV radiation derive from the combined action of UVB and UVA: direct damage by UVB and to a less extent by UVA to DNA through cyclobutane pyrimidine dimer formation as well as the indirect oxidative damage induced by UVA, modulated by the efficiency of DNA repair pathways such as nucleotide excision repair (Ikehata and Ono 2007). UV radiation also suppresses the immune system by inducing immunosuppressive mediators and by interfering with immune responses of antigen-presenting cells (Halliday and Rana 2008).

A multitude of epidemiologic studies support the causation of cancers of the skin by solar UV radiation in white populations (IARC 2012), ranging from descriptive studies showing positive associations with birth and/or residence at low latitudes and rare occurrence at non-sun exposed body sites, to analytic studies showing that biologic indicators of excessive sun exposure, namely multiple sunburns (throughout life, but especially in childhood) and actinic keratoses, are significant risk factors (Whiteman et al. 2001; Fears et al. 2002; Chang et al. 2009). Further, there is now evidence from randomized controlled trials that regular application to the skin of a broad-spectrum sunscreen that filters at least 95% of UVB and a proportion of UVA (i.e. sunscreen with a Sun Protection Factor (SPF) of at least 15+), protects against actinic keratoses, SCC, and melanoma (Thompson et al. 1993; Green et al. 1999, 2011b). Convincing evidence is now also available from cohort studies and meta-analyses that the use of tanning beds increases the risks of all three major skin cancers, BCC, SCC, and melanoma, particularly if exposure occurs during the first three decades of life (Boniol et al. 2012; IARC (Working Group on Artificial Ultraviolet Light and Skin Cancer) 2007; Olsen and Green 2012; Wehner et al. 2012; Zhang et al. 2012).

Beneficial effects (UV)

Besides the modest photoprotection against further UV-induced skin damage provided by a suntan to pale skin, UV exposure enhances vitamin D synthesis which is essential to bone health. Beyond bone health, conclusive evidence of benefit of UV radiation mediated through vitamin D or otherwise, is not presently available, however (Institute of Medicine 2011;

Thacher and Clarke 2011; Allinson et al. 2012; LeBlanc et al. 2015). When a systematic review of vitamin D and cancer was performed by IARC in 2008, benefits were inconclusive and did not outweigh the harms (IARC 2008), and later systematic reviews have been consistent with this (Gandini et al. 2011).

Policy and prevention (UV)

Limiting exposure to solar UV

The Global Solar UV Index (UVI) is a unitless quantity estimated on a daily basis that describes the maximum intensity of solar UV radiation received on the Earth's surface at a nominated location (Allinson et al. 2012). Developed jointly by the WHO, the United Nations Environment Programme, the World Meteorological Organization, and the ICNIRP, the UVI serves to raise public awareness about the amount of harmful UV radiation present at a specified location (WHO 2002). Guidance about appropriate sun protection measures is also provided in line with standard recommendations of cancer control agencies worldwide on how best to avoid solar UV exposure for the primary prevention of skin cancer. These are: limit exposure during midday hours; seek shade; wear protective clothing including a broad-brimmed hat to protect the eyes, face, and neck; protect the eyes further with wrap-around sunglasses; use and reapply broad-spectrum sunscreen of at least SPF 15+ liberally; and protect babies and young children from intense sunlight (WHO 2002). The specific use of sunscreen is advocated as an adjunct to physical protection measures (shade; clothing cover) and sunscreen should be reapplied after sweating, swimming, and long periods in the sun. Despite much evidence from ecologic and observational studies about sun exposure and sunscreen use, vitamin D, and human health outcomes, currently there is an absence of evidence from randomized controlled trials about their quantitative relationships, and thus, there is as yet no established basis on which to include vitamin D considerations in sun protection recommendations (Allinson et al. 2012).

Limiting exposure to sunbeds

Many countries have enacted legislation to more tightly regulate the sunbed industry and limit people's exposure to this source of UV radiation. Sunbeds

are banned in Brazil and Australia, and legislation prohibiting use by those under 18 is in place in France, Spain, Portugal, Germany, Austria, Belgium, England, Wales, Northern Ireland, and Scotland, Canada, and the United States (Pawlak et al. 2012). These regulations need to be reinforced by warnings from health professionals and education about the risks of indoor tanning (WHO 2017), so that young people in particular are aware that their use of sunbeds for short-term cosmetic tanning materially raises their skin cancer risk (Olsen and Green 2012).

Limiting occupational exposures

ICNIRP recommends upper limits of exposure to UV in occupational settings, outdoor and indoor, to protect both the skin and the eyes of workers (ICNIRP 2004). It is recognized that the risks of UV exposure of the skin differ greatly depending on skin colour: skin protection must be emphasized for white-skinned people, while higher average threshold exposure is allowed for Asian and Black skin types. Eye protection against UV is emphasized for all skin types.

For the outdoor worker, exposure of the skin depends upon the work tasks and posture, exposure duration, the particular environment, time of day, and season, such that all of these factors need to be taken into account in establishing appropriate control measures. Under most situations, ocular UV exposure does not exceed the limits for even long exposure duration unless in environmental conditions where ground reflectance is unusually high (ICNIRP 2010). Standard protective clothing and headwear can be complemented by application of broad-spectrum sunscreen, while UV-protective goggles can effectively reduce ocular UV exposure from high-reflectance surfaces like snow. For indoor workers' exposure to artificial sources such as UVC-emitting lamps for sterilizing work areas in hospitals, the food industry, and laboratories, or UV lasers, safety precautions include engineering (structural) and administrative controls and Personal Protective Equipment and training. Educating individual workers about the risks of excessive UV exposure is also of paramount importance (ICNIRP 2010).

Ionizing radiation

Ionizing radiation consists of high frequency electromagnetic radiation—X-rays and gamma-rays—or of subatomic particles such as alpha-particles (^{4}He nuclei), beta-particles (electrons), neutrons, protons, pions, muons and atomic nuclei (such as ^{12}C ions). For radiation to be ionizing it must have high enough energy to eject electrons from atoms or molecules, thus creating electrically charged ions. Electrically charged particles (e.g. alpha- and beta-particles) are directly ionizing, whereas electrically neutral particles (e.g. gamma-rays and neutrons) are ionizing because they produce charged particles on interacting with matter. Ionizing radiation is capable of causing DNA strand breaks either by directly interacting with DNA or through the production of chemical free radicals. The energy deposited in matter by ionizing radiation is measured in gray (Gy), 1 Gy being 1 J/kg, which is the absorbed dose of radiation (National Research Council (NRC) 2006; ICRP 2007; United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) 2008, 2010).

The amount of energy transferred by particles per unit track length when passing through matter is called the linear energy transfer (LET) of the radiation. For example, gamma- and X-rays, electrons, and muons are sparsely ionizing— low LET— radiations because relatively few ionization events occur along their paths. On the other hand, alpha-particles, energetic neutrons, and accelerated heavy charged nuclei (e.g. ^{12}C) generated by synchrotrons are termed high LET radiations because they transfer a relatively large amount of energy per unit track length, producing a high density of ionization. Measurement units commonly used are defined and listed in Table 7.2.1.

Table 7.2.1 Quantities and units of ionizing radiation (ICRP 2007)

Quantity dose	Unit	Definition
Absorbed dose	gray (Gy)	Energy deposited in matter (= 1 J/kg)
	rad (obsolete unit)	1 rad = 100 erg/g = 0.01 Gy = 1 cGy
Equivalent dose	sievert (Sv)	Absorbed dose multiplied by the radiation weighting factor, w_R, for the particular type of radiation. Defined in the context of radiological protection against low-level exposure
	rem (obsolete unit)	1 rem = 0.01 Sv = 1 cSv
Effective dose	sievert (Sv)	Sum of equivalent doses, each multiplied by the tissue weighting factor, w_T, for the particular organ/tissue irradiated. Defined in the context of radiological protection against low-level exposure
Collective effective dose	person-Sv	Sum of the individual effective doses for a population. Defined in the context of radiological protection against low-level exposure
Committed effective dose	sievert (Sv)	Cumulative effective dose to be received over a given period from a given intake of radioactive material. Defined in the context of radiological protection against low-level exposure
Radioactivity	becquerel (Bq)	The unit of activity, one radioactive transformation per second
	curie (Ci) (obsolete unit)	37 billion disintegrations per second (= 37 GBq)

Source: data from International Commission on Radiological Protection (ICRP), *The 2007 Recommendations of the International Commission on Radiological Protection*, ICRP Publication 103, Copyright © 2007.

For the purposes of radiological protection, in the context of low doses (<100 mGy of low LET radiation) or low dose rates (<0.1 mGy/min, as an hourly average, of low LET radiation), the absorbed dose is weighted by the different ionization densities of the various types of radiation and by the different radiosensitivities of the various human organ/tissues, reflecting the overall health detriment posed by such exposures. The equivalent dose is

given by the sum of the absorbed doses (averaged over a tissue) each multiplied by the radiation weighting factor, w_R, for the particular types of radiation involved, and the effective dose is the sum of the equivalent doses received by different tissues with each equivalent dose weighted by the tissue weighting factor, w_T—both equivalent and effective doses are measured in sievert (Sv). For low-level exposure, the effective dose gives the same overall risk of an adverse health effect as a uniform whole-body dose of gamma radiation. It is used in radiological protection when different organs/tissues receive different doses, possibly from radiations with different radiation weighting factors (ICRP 2007).

Sources and environmental levels (ionizing radiation)

Exposure to natural background radiation is ubiquitous. Additional exposure occurs from anthropogenic sources, mainly for the purposes of medical diagnosis. Overall, the world-averaged individual effective dose from naturally occurring sources is about 2.4 mSv/year, with a typical range of 1.0 to 13 mSv/year (UNSCEAR 2010). This represents about 80% of the global average individual effective dose, the ~0.6 mSv/year received from artificial sources being dominated by medical exposures (UNSCEAR 2010). The different sources contribute the fractional amounts as summarized in Figure 7.2.2. The rapid advance in radiodiagnostic technology (such as CT scanning and nuclear medicine) has led to a comparatively large increase in doses from medical sources in developed countries (UNSCEAR 2010).

Naturally occurring sources

In addition to external sources of radiation, such as cosmic-rays originating from outside the Earth and terrestrial gamma-rays from naturally occurring radioactive materials in the environment, radionuclides are inhaled or ingested, irradiating the body from within, and the inhalation of the radioisotopes of radon and their radioactive decay products contributes on average more than 50% of the effective dose from natural sources. Radon-222 is the main source of radon exposure and is produced by the decay via alpha-particle emission of radium-226, which is a component of the radioactive decay chain of naturally occurring uranium-238; rarer radon-220 is part of the decay chain of naturally occurring thorium-232. When radon is inhaled the dose is largely from alpha-particles to the bronchial epithelium,

with a consequent risk of lung cancer. The ingestion of naturally occurring radionuclides is mainly through the presence of the decay products of uranium-238 and thorium-232, and of long-lived radionuclides such as potassium-40, in food and drink. When cosmic-rays strike the upper atmosphere radionuclides are formed, mainly tritium (hydrogen-3) and carbon-14, and these enter the body largely through the consumption of food and drink.

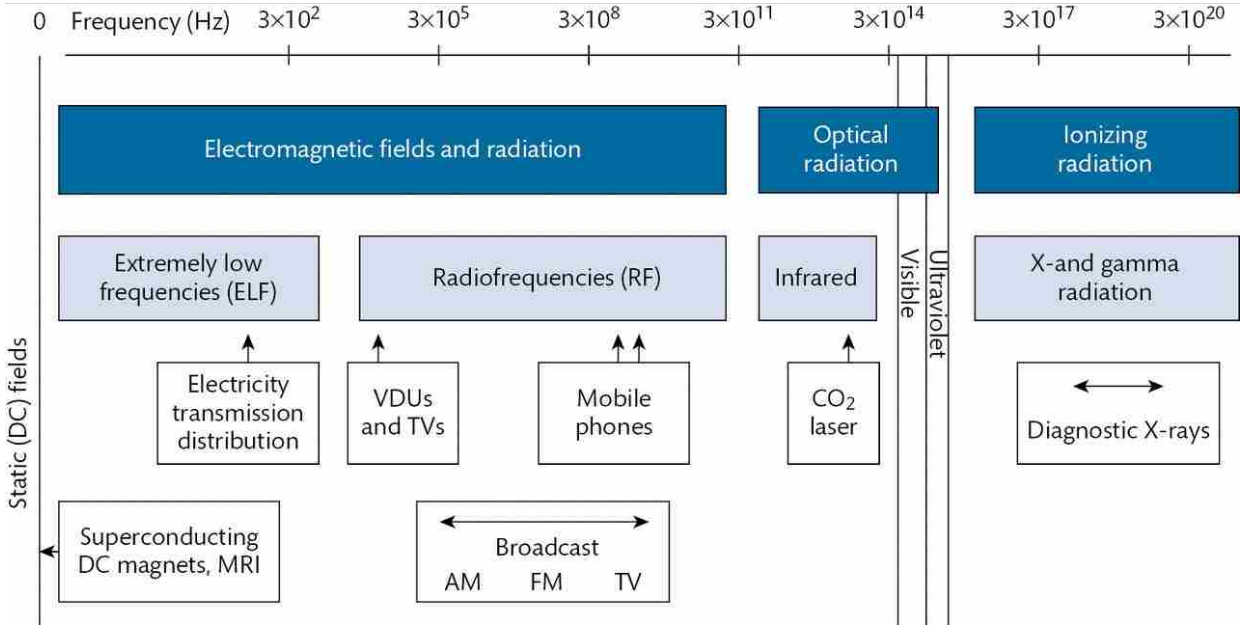

Fig. 7.2.2 Worldwide average annual individual effective dose (mSv) (UNSCEAR 2010).
Source: United Nations Scientific Committee on the Effects of Atomic Radiation 2010, 'Summary of low-dose radiation effects on health', in UNSCEAR 2008 Report to the General Assembly, with Scientific Annexes, United Nations, New York.

There are important variations in the natural background dose depending on factors such as the nature of rock and soils, building materials, and altitude. There exist on Earth high natural background radiation areas where annual effective doses can exceed 10 mSv and even 100 mSv (UNSCEAR 2010). These elevated levels may be due to gamma radiation, such as from the monazite sands of the coast of Kerala in India, but mainly they are due to gaseous radon entering buildings and producing high concentrations in air. Concentrations of radon and its decay products in some houses in the most affected areas of the world are sufficiently raised that measures are necessary

to reduce the consequent risk of lung cancer to acceptable levels. Cosmic radiation levels are increased at high altitudes due to decreased shielding by the atmosphere—air travel therefore raises the dose received from cosmic-rays, but with the exception of frequent travellers (and aircrew), this forms a relatively small increase in the overall dose from natural sources of radiation. Doses received occupationally and the numbers of workers involved worldwide are shown in Table 7.2.2.

Table 7.2.2 Global occupational radiation exposures (UNSCEAR 2010)

Source of exposure	Average annual effective dose (mSv)	Number of monitored workers worldwide (thousands)
Man-made sources [1]		
Nuclear fuel cycle (including uranium mining)	1.0	660
Industrial uses of radiation	0.3	869
Military activities	0.1	331
Medical uses of radiation	0.5	7,440
Miscellaneous	0.1	565
Total from man-made sources	0.4	9,865
Enhanced natural sources [2]		
Aircrew	3.0	300
Mining (other than coal)	3.0	4,600
Coal mining	2.4	6,900
Other workplaces	4.8	1,250
Total from natural sources	2.9	13,050

[1] 2000–2002
[2] 1995–2002

Data from (UNSCEAR 2010).

Man-made radiation sources

The main man-made global contribution to environmental exposure has come from radioactive fallout from the testing of nuclear weapons in the atmosphere, mainly during the late 1950s and early 1960s. The world average annual effective dose reached a peak of 0.11 mSv in 1963, and since then it has decreased to about 0.005 mSv in 2000, most of this dose is now coming from carbon-14 (UNSCEAR 2010). Other contributions are from the generation of electricity from nuclear energy and the production of nuclear weapons, and also from naturally occurring radionuclides in the discharges from fossil-fuelled power stations and other industrial plants, such as phosphate processing factories. Doses to members of the public from these exposures are now generally low at around a μSv. Doses to workers in the nuclear industry and in other occupations (e.g. industrial radiographers) have fallen over the years with improved radiological protection measures. The worldwide average annual dose in the nuclear industry is now about 1 mSv. Modern technological advances have led to other sources of exposure, such as smoke detectors and security scanners, although the doses received from these are almost always minute.

Some potential sources of exposure have raised public concern, such as lost medical or industrial radiation sources, deliberate contamination of items such as foodstuffs with radioactive materials, or ‘dirty bombs’. ‘Dirty bombs’ (a type of ‘radiological dispersion device’) spread radioactive materials by using conventional explosives (WHO 2003), but it is difficult to assess just how dangerous these terrorist weapons would be in terms of radiological effects, and it is likely that the greatest impact would be psychological as a result of fear and panic.

Exposure from medical procedures

Modern diagnostic radiography assures earlier, more precise diagnosis and monitoring of the progression of a large number of diseases. Screening procedures (such as mammography) are beneficial for specific populations who are at a higher risk from certain diseases (such as breast cancer). Diagnostic radiography using conventional X-ray examination, CT scanning, and positron emission tomography (PET) have significantly improved the staging and accuracy of diagnosis. In addition, a number of interventional radiologically-driven procedures (such as angioplasty) introduced in the last

10–20 years, contribute significantly to the effectiveness of treatment of serious diseases of the cardiovascular and central nervous systems and other organs. Such technological improvements can be critically important in effecting cures, but involve relatively high exposure, and therefore should be used with care.

In recent years the use of nuclear medicine and in particular CT scanning has increased to a marked extent in economically developed countries. This increase is illustrated by the average annual effective dose to members of the population of the United States from medical procedures (mainly from diagnostic exposures), which was 0.53 mSv in the early-1980s, but had risen to 3.0 mSv in 2006, a level that is comparable to the average annual effective dose received from natural sources. The doses received from medical procedures are dependent on economic development: world-averaged individual dose from medical exposures during 1997–2007 was 0.62 mSv/year, but in countries with advanced healthcare systems it was 1.92 mSv/year (UNSCEAR 2010). The number of procedures carried out in the United States during 2006 in each category of diagnostic and interventional procedures, together with the average effective dose received per procedure, is given in Table 7.2.3

Table 7.2.3 Estimated number of procedures, and the average effective dose received, in each category of diagnostic and interventional procedures carried out in the United States during 2006 (NCRP 2009)

Category	Number of procedures (million)	Average effective dose per procedure (mSv)	Collective dose (person-Sv)
Computed tomography (CT)	67	6.6	440,000
Conventional radiography and fluoroscopy	293	0.3	100,000
Interventional fluoroscopy	17	7.5	128,000
Nuclear medicine	18	12.8	231,000
Total	395	2.3	899,000

Radiation therapy is based on the ability of ionizing radiation to kill cells, and radiation can target a particular group of cells, such as cancerous cells. Radiotherapy saves many lives every year, and in the case of palliative treatment, substantially reduces suffering. There are also some non-malignant diseases whose treatment by radiation is a method of choice. Most of the side effects of conventional radiotherapy are predictable and expected, arising from the unintentional irradiation of cells outside the target tissues, and one of the aims of modern IMRT (intensity modulated radiation therapy) is to reduce the side effects to a minimum by sparing normal tissues (Hall 2006). However, radiotherapy inevitably leads to some degree of irradiation of healthy tissues and to consequent risk of adverse health effects. This is particularly relevant for deeply-seated tumours, tumours closely located to critical organs, and paediatric tumours. One newly-emerging method is the use of charged particles (e.g. protons and ^{12}C ions), with their positive physical and radiobiological properties, which allows highly conformal treatment of various kinds of tumours while delivering minimal doses to large volumes of surrounding healthy tissues. This means that they can cause severe damage to the DNA in cancer cells while sparing both traversed and deeper healthy tissue. This characteristic also enables them to be used for a more accurate irradiation of the tumour (Rosen 2001).

Recommendations for medical exposure

Medical exposures are intended to provide a direct benefit to the exposed individual. If the practice is justified and the protection optimized, the dose in the patient will be as low as is compatible with the medical purposes. Therefore, dose limits are generally not applied to medical exposures. However, there is considerable opportunity for dose reductions in diagnostic radiology using the techniques of optimization of protection, and this is important since the second largest exposure to typical individuals is from medical exposures, and this is increasing particularly in the developed countries.

The risk from diagnostic radiography is a particularly important consideration for children—they are still developing and are more sensitive to radiation-induced cancer than adults; in addition, they have a longer prospective life span, and hence, the period over which potential long-term side effects may arise is greater (Brenner et al. 2001; WHO 2005). Therefore, care should be taken to minimize the number of unnecessary X-ray examinations, including dental X-ray examinations, and in optimizing the CT exposure settings when this procedure is indicated.

Health effects (ionizing radiation)

Ionizing radiation causes two categories of adverse health effects: tissue reactions (also known as deterministic effects) and stochastic effects (ICRP 2007). Tissue reactions are caused by the ability of radiation to kill cells—if sufficient cells are killed then the tissue reaction occurs—and tissue reactions are characterized by a threshold dose below which the effect does not occur and above which the tissue reaction increases in severity with the dose received (as more cells are affected). Stochastic effects are caused by non-lethal cell modification, which may develop into a cancer if the affected cell is somatic or into a hereditary abnormality if the affected cell is a germ cell. Stochastic effects are understood to have no threshold dose, and at low doses or low dose rates the risk is assumed to be directly proportional to the received dose, although this is not universally accepted. The overall risk of stochastic effects is dominated by the risk of cancer in the exposed individual (ICRP 2007).

Ionizing radiation causes damage to DNA either through direct physical interaction with DNA or through the nearby creation of free radicals that

then chemically react with DNA. These interactions cause strand breaks in the DNA, and ionizing radiation is particularly efficient at producing clustered (i.e. localized) damage and consequently double strand breaks. DNA repair mechanisms attempt to deal with the strand breaks caused by ionizing radiation, but double strand breaks are especially difficult to repair accurately. Heavy damage to DNA from high acute doses of radiation often leads to a loss of DNA integrity that is sufficiently serious to lead to cell death, and when a particular proportion of cells in a tissue is killed then a tissue reaction occurs; the greater this proportion the more severe the tissue reaction. A cell may survive the DNA damage caused by radiation because the DNA is repaired correctly, but a cell may also survive with the DNA damage misrepaired, and this is understood to be the origin of the risk of cancer (in somatic cells) and hereditary effects (in germ cells).

The dose-response for stochastic effects is conventionally thought to be produced by a combination of the single traversal of the cell nucleus by a track of radiation and multiple traversals by independent tracks. The former occurs at low doses or low dose rates of sparsely ionizing radiation and produces a linear term in the dose-response, while the latter occurs at moderate and high doses delivered at a high dose-rate and leads to an upward curving quadratic term; this is the mechanistic origin of the Dose and Dose-Rate Effectiveness Factor (DDREF) of greater than 1 (conventionally, a value of 2), whereby the effect per unit dose (the slope of the dose-response) is greater at moderate-to-high acutely delivered doses. At high acute doses, cell killing becomes more likely, and the slope of the dose-response reduces as a consequence (since dead cells cannot contribute to the risk of stochastic effects). The linear no-threshold dose-response assumes that at low doses or low dose rates the risk of non-lethal DNA damage of relevance to stochastic effects is directly proportional to the dose, and therefore, to the overall number of tracks crossing cell nuclei.

For high LET radiations, the density of ionization is such that the passage of a single particle through a cell nucleus does sufficient damage to the DNA that only a linear term in the dose-response is apparent. Indeed, at the cellular level, the passage of a single alpha-particle track is a high dose event, with a reasonable probability of inducing cell death, so the passage of two alpha-particles is most likely to kill the cell. Thus, the dose-response for high LET radiations is characterized by linearity, with a slope greater than that for the same absorbed dose produced by low LET radiations (due to the

higher ionization density), followed by a reduction in slope at high doses due to cell killing.

However, this picture is a greatly simplified version of reality, the biological mechanisms involved being very complex. For example, it assumes that DNA repair following acute low doses or low dose rates of low LET radiation, producing just a few electron traversals of a cell nucleus, is not much more efficient (conventionally, twice as efficient—a DDREF of 2) than that following acute moderate doses, producing many electron traversals, and this assumption may not be correct. Further, there is evidence that epigenetic mechanisms may play a role in radiation-induced risk, in a way that is as yet unclear, and that these mechanisms may differ between high doses and low doses.

Some argue that since low doses produce a degree of DNA damage that is comparable to the overall level of damage that is constantly occurring through background biochemical processes, it is unlikely that low doses are harmful because the radiation-induced damage is ‘swept up’ by routine repair. Going even further, some argue that low doses of radiation stimulate the immune system, and so are beneficial because damage is repaired that would not have been otherwise (so-called radiation hormesis). Nonetheless, the ‘clustered’ nature of the damage caused by the passage of ionizing radiation through a cell nucleus must be taken into account in such a comparison. On the other hand, some mechanisms of damage may be more effective at low doses than at moderate doses, leading to a supralinear dose-response, and the bystander effect (whereby a cell hit by radiation adversely influences neighbouring cells that were not directly hit) is one example of such a mechanism because it affects more bystander cells at low doses than at moderate doses, where the effect is saturated because nearly all cells are hit. This serves to illustrate the complexity of radiobiology, and why risk estimates are still dominated by empirical epidemiological findings (ICRP 2007).

It has been known for many decades that brief exposure to a dose of several gray leads to death through the killing of sufficient numbers of cells in vital tissues such as the red bone marrow (i.e. death is caused by tissue reactions in radiosensitive tissues). An example from recent decades is the 28 emergency workers attending the Chernobyl nuclear reactor accident in Ukraine in 1986 who died within a few months as a result of the high doses they received over a short period. Another example is the deliberate

poisoning with a substantial dose of the alpha-emitter polonium-210 of Mr. Litvinenko in London in 2006. Other tissue reactions include skin burns, epilation, permanent and temporary sterility, depression of haematopoiesis, eye lens opacities and cataracts, and tissue necrosis.

Cancer (ionizing radiation)

Radiation has always been a natural part of our environment, and the types of radiation emitted from anthropogenic sources are fundamentally the same as those emitted from natural sources. At present it is not possible to distinguish between cancers resulting from radiation exposure (whether from man-made or naturally occurring sources) and those arising from other causes (NRC 2006; ICRP 2007; UNSCEAR 2008, 2010; IARC 2012). Consequently, in the absence of being able to determine the risk to human health from exposure to ionizing radiation from fundamental radiobiological principles, risk estimates must be derived empirically from epidemiological studies of suitably exposed groups of humans, augmented by an incomplete knowledge of radiobiological mechanisms. The evidence that has been constructed from radio-epidemiological studies is substantial, and with the possible exception of tobacco, no other exposure has been studied so extensively. These epidemiological studies fall into four broad categories: studies of the Japanese survivors of the atomic-bombings, those exposed for medical purposes either therapeutically or diagnostically, occupational exposure, and those exposed environmentally (NRC 2006; ICRP 2007; UNSCEAR 2008, 2010; IARC 2012).

The experience of the survivors of the atomic-bombings of Hiroshima and Nagasaki in 1945 provides the principal (but certainly not the only) epidemiological evidence on which radiation risk estimates are based. A large cohort study, the Life Span Study (LSS), was established from information gathered during the Japanese national census in October 1950, and analyses of data generated by the LSS continue today (Preston et al. 2007; Ozasa et al. 2012; Hsu et al. 2013). The LSS consists of about 93,500 survivors, around 86,500 of whom have individually estimated tissue-specific doses—considerable effort has been expended on the reconstruction of tissue-specific doses received during the bombings (mainly from γ-rays, but a component from neutrons), the latest database being the Dosimetry System 2002 (DS02), which has recently undergone a minor revision

(DS02R1) (Cullings et al. 2017). Of the LSS subjects, ~48,000 received non-trivial doses (>5 mSv), and of these ~18,000 received doses >100 mSv, and ~2,400 doses >1 Sv; almost 2/3 of the non-trivially exposed survivors received doses <100 mSv (i.e. low acute doses). At the end of the last mortality follow-up (2003), 58% of the LSS subjects had died, and 24% of the deaths were due to cancer; 527 solid cancer deaths (8% of such deaths among non-trivially exposed survivors) are estimated to be attributable to radiation exposure during the atomic-bombings (Ozasa et al. 2012). Approaching half of the 204 leukaemia deaths before 2001 among the LSS survivors receiving doses >5 mSv have been attributed to radiation (Preston et al. 2004), so overall, around 10% of cancer deaths in the atomic-bomb survivors are estimated to have been attributable to radiation from the bombings. As well as mortality, cancer incidence is ascertained in the LSS through two specialist registries, the most recent analysis of solid cancer incidence covering the period 1958–2009 (Grant et al. 2017), while the latest findings of the incidence of leukaemia, lymphoma, and multiple myeloma are from an analysis covering the period 1950–2001 (Hsu et al. 2013). The latest study of solid cancer incidence has revealed a difference between the sexes in the dose-response for all solid cancers combined: for males the dose-response is curvilinear upwards while for females it is linear (Preston et al. 2007). The reasons for this difference are being investigated. In a subset of the LSS, the Adult Health Study (AHS), survivors participate in regular medical examinations to record clinical parameters such as blood pressure. Other relevant cohorts are those who were exposed *in utero* and the survivors' offspring who were conceived after the bombings, the latter group providing information on the risks of the hereditable effects of exposure.

Early support for the initial findings of the studies of the Japanese atomic-bomb survivors came from investigations of long-term health effects among patients treated with radiotherapy, in particular British patients irradiated for ankylosing spondylitis and US women treated with radiation for cancer of the uterine cervix (McLean et al. 2017; UNSCEAR 2008). Now there is evidence deriving from a wide range of radio-therapeutic treatments such as various groups of cancer survivors, children irradiated for ringworm of the scalp or haemangioma of the skin or for an enlarged thymus, and patients injected with the alpha-emitter radium-224. Patients exposed to radiation for diagnostic purposes are providing increasingly useful information as the use of CT scans increases, but those X-rayed to monitor treatment for

tuberculosis or for scoliosis, and foetuses exposed during an abdominal X-ray examination of the pregnant mother have already provided valuable evidence on the risks of low-level exposures. A recent large cohort study of British children who received at least one CT scan found evidence of an increased risk of brain tumours and leukaemia that was related to the dose of radiation estimated to have been received from the scans (Pearce et al. 2012). An interesting group of patients is those injected with the radiographic contrast medium Thorotrast, which unfortunately was thorium-based and therefore radioactive and gave large doses to certain tissues, such as the liver and red bone marrow, leading to excess liver cancers and leukaemias.

Although the findings of studies of those exposed for medical purposes form a valuable complement to the evidence from studies of the atomic-bomb survivors, medical studies need to be interpreted with care since exposure occurred due to a known or suspected disease. For example, a CT scan may have taken place because of an undiagnosed cancer, so that the cancer caused the CT scan, not the reverse (so-called reverse causation). Similarly, a certain medical condition may predispose to cancer, but may also lead to other diseases that require a greater frequency of CT scans, leading to ‘confounding by indication’. These considerations have led to difficulties of interpretation of the findings of low-dose diagnostic exposures because the predicted risk of such exposures is small relative to the background risk of cancer so that subtle biases and confounding can lead to spurious associations with radiation. Radiotherapy usually involves localized high (cell killing) doses, which can affect incidentally irradiated healthy tissues and lead to a reduction of radiation-induced cancer risk in these tissues; concomitant chemotherapy can also be a difficulty of studies of those receiving radiotherapy.

Radiologists and radiographers have been subjects of study since the early uses of radiation in medicine, and US radiologists provided the first indication that radiation could cause leukaemia (March 1944). Of particular interest are groups of underground hard-rock miners (for example, uranium and tin miners) who inhale the radioactive gas radon and its decay products which irradiate the lungs (mainly with alpha-particles); and in the past, exposures have been high. Workers (mainly young women) who applied radium-based luminous paint to watch and instrument dials inadvertently ingested radium (an alpha-emitter) through the habit of licking the tips of

paintbrushes (‘tipping’), and some workers ingested large quantities of radium, which deposits in bones and led to an excess of bone cancers. Of increasing importance is the evidence obtained from the study of groups of nuclear industry workers, especially those who worked during the early years of the industry when doses were comparatively high relative to those received today. Large worker-studies are providing valuable information on the effects of protracted low-level exposure, and international collaborations have the potential to produce statistically powerful results. The International Nuclear Workers Study (INWORKS) is a recent example of such a collaboration, and has reported radiation-related increases in the risk of leukaemia and solid cancers (Leuraud et al. 2015; Richardson et al. 2015, 2018). Special cases are those workers involved in dealing with emergencies, such as the ‘liquidators’ who were brought in to deal with the aftermath of the Chernobyl accident in 1986 (Kashcheev et al. 2015), and those from the early years of operations at the Mayak nuclear complex in Russia who were particularly highly exposed to both external sources of radiation and plutonium, an alpha-emitter that was inhaled in relatively large amounts during the early weapons production programme of the former USSR (Sokolnikov et al. 2015; Kuznetsova et al. 2016).

Radon in homes has been a subject of substantial scientific attention because globally this is the source of the largest exposure to radiation for the great majority of people. Large case–control studies that take into account the important contribution of risk posed by cigarette smoking, have examined the risk of lung cancer arising from residential exposure to radon, and appropriately combined findings from these studies have produced radon-related risk estimates that are compatible with those obtained from underground hard-rock miners (ICRP 2010; McLean et al. 2017). Exposure to other sources of natural background radiation, in particular terrestrial gamma radiation, has also been studied, notably in those parts of the world where such exposures are materially greater than the global average. A study of cancer incidence in Kerala (India) has not found an excess cancer risk related to radiation exposure, although the power of this study is presently limited and the findings are compatible with those of the LSS (Nair et al. 2009). A large British case–control study concentrating on childhood leukaemia has found evidence of an excess risk from background gamma radiation that is consistent with risk models derived from the Japanese

atomic-bomb survivors (Kendall et al. 2013), but a similar study in France did not find an excess risk (Demoury et al. 2017).

Radioactive contamination from accidental and routine discharges from nuclear installations has been another area of study, radioactive releases from the accident at Chernobyl (UNSCEAR 2018) and substantial pollution of the Techa River by liquid effluent from the Mayak complex being notable examples (Krestinina et al. 2013; Davis et al. 2015). Radioiodine released during the Chernobyl accident in 1986 led to a large excess of thyroid cancer among those highly exposed (largely through the consumption of heavily contaminated milk) as children, and excess leukaemias and solid cancers have been found in the Techa River residents. The releases during the Fukushima nuclear reactors accident in 2011 provide another opportunity for study, although it would appear that doses are not sufficiently large for any effects to be detectable (WHO 2012a, 2012b). The Fukushima accident provides another illustration of the caution that is required in the interpretation of health data, in that the Japanese government established a health survey in Fukushima Prefecture that included a thyroid screening programme for all those at a young age at the time of the accident. An excess of thyroid cancer has been found by this screening programme, but it is most unlikely that this is as a result of radiation exposure during the accident, and probably due to screening using sensitive ultrasonography detecting cancers that would have been present but undiagnosed in the absence of the screening, an effect that has been found elsewhere (Ahn et al. 2014).

Fallout from atmospheric nuclear weapons testing, especially at its peak in the late-1950s and early-1960s, has provided another source of exposure for study, and those resident in the vicinity of weapons testing sites (such as the Semipalatinsk Testing Site in present-day Kazakhstan) are of particular interest. Global fallout has not influenced childhood leukaemia incidence much beyond the level predicted by standard models, showing that intakes of fallout radionuclides do not have the pronounced leukemogenic effect that has been suggested by some (Wakeford et al. 2010). A group of Taiwanese residents was irradiated by gamma-rays from ^{60}Co-contaminated steel accidentally used in building construction, and this group is being followed (Hsieh et al. 2017). There is some evidence of an excess of leukaemia and breast cancer.

Epidemiological studies have clearly established that acute exposure to moderate and high doses of ionizing radiation (>100 mGy of sparsely

ionizing radiation) increases the risk of cancer (NRC 2006; ICRP 2007; UNSCEAR 2008, 2010; IARC 2012; McLean et al. 2017) However, all types of cancer do not have equal sensitivity to radiation-induction—acute leukaemia, thyroid, and female breast cancer have a high sensitivity, whereas chronic lymphocytic leukaemia, Hodgkin lymphoma, and melanoma of the skin have a low sensitivity, with other cancers falling somewhere in between from higher (e.g. lung and colon cancers) to lower (e.g. pancreatic and prostate cancers) sensitivity. Leukaemia was the first cancer to be definitively linked to radiation exposure when a clear excess risk of the malignant disease was detected in the LSS of Japanese atomic-bomb survivors in the early-1950s (although unusually high numbers of cases were reported by alert clinicians in the late-1940s, before the LSS was established), and there had been earlier reports of elevated levels of leukaemia among radiologists (March 1944), which had been difficult to interpret at the time. As the follow-up of the atomic-bomb survivors progressed, raised mortality and incidence of other cancer sites were found to be related to exposure, and this evidence was supplemented by other exposed groups, such as an increased risk of a number of solid cancers among patients treated with radiotherapy for a variety of diseases, a marked excess of bone cancer among those groups with high intakes of radium, an excess risk of lung cancer among underground hard-rock miners exposed to radon, and an excess risk of liver cancer among the Thorotrast patients with high body burdens of thorium (McLean et al. 2017). Recently, the Chernobyl accident has produced a notable excess risk of thyroid cancer among those who as children inhaled and ingested high levels of radioactive iodine released during the accident, an excess that is compatible with that found among those exposed as children to external sources of radiation.

The most recent analysis of leukaemia mortality among the LSS cohort found that a linear-quadratic dose-response best described the full range of data, and that the excess relative risk was 3.1 (95% CI: 1.8–4.3) at 1 Gy red bone marrow dose and 0.15 (95% CI: –0.01–0.31) at 0.1 Gy, based on 318 deaths (Ozasa et al. 2012). About half of the leukaemia deaths among the non-trivially exposed (>5 mGy) survivors are attributed to irradiation during the bombings. However, modelling demonstrates a marked variation of risk with age-at-exposure and time-since-exposure: for young children, the excess relative risk (ERR, the proportional increase in risk) rises to a peak of ~50 some 7 years after exposure and then falls away to ~5 some 30 years

after exposure—a temporal wave of excess risk—while for exposed adults this wave is hardly apparent, with the ERR remaining below 5 at all times after exposure. From the latest data set for mortality from all solid cancers (malignant diseases other than leukaemia, lymphoma, and multiple myeloma) among the survivors, a linear dose–response fits the data best, with a slope of the ERR for solid cancer mortality for a survivor exposed at age 30 years and at an attained age of 70 years of 0.47 (95% CI: 0.38–0.56) Gy^{-1}, based upon almost 11,000 deaths. The ERR coefficients for leukaemia and solid cancer incidence are similar to those for mortality (Preston et al. 2007; Ozasa et al. 2012; Hsu et al. 2013), but the latest solid cancer incidence study has found a significant difference in dose-response between the sexes (Grant et al. 2017). As mentioned earlier, there is notable variation in the ERR/Gy for individual sites of cancer, the ERR for the incidence of breast, thyroid, and non-melanoma skin cancers being high while that for cancers of the rectum and uterus are low.

Risk models have been developed from the cancer data for the Japanese atomic-bomb survivors, supplemented by other data sources where these are found to make a useful contribution to evidence, such as for leukaemia and for thyroid and breast cancers following exposure for medical therapy. Lung cancer among radon-exposed underground hard-rock miners has provided a valuable source of information on the risk of radon-induced lung cancer, which is compatible with the risk of lung cancer among those exposed residentially to, in general, much lower levels of radon. The influence of tobacco smoke upon the risk of lung cancer is especially important to take into account in such studies, and it would appear that radiation and cigarette smoke interact to produce a combined risk of lung cancer that is more than additive, so that smokers are at a greater risk of radon-induced lung cancer than non-smokers.

In general, the findings of the studies of the Japanese atomic-bomb survivors are compatible with those from other exposed groups, although comparisons are often not straightforward. For example, doses from radiotherapy are usually localized and high, with the objective of killing the target cells, but the unintentional irradiation of healthy cells can also lead to their being killed and thereby to a reduction in the risk per unit dose of cancer. Doses away from the target are received from scattered radiation and are difficult to compute accurately, although modern dose reconstruction methods are improving dose estimates. Of growing importance are studies of

acute low doses or protracted low dose rates, because these exposure circumstances directly test the assumptions required for everyday radiological protection. Preliminary findings of such studies, e.g. of patients receiving CT scans, those living in areas affected by radioactive contamination, or nuclear industry workers, indicate that there is an increased risk from low doses/dose-rates (at least, for some types of cancer, notably leukaemia), but that this risk is not greatly different from the predictions of conventional risk models.

Other outcomes (ionizing radiation)

Epidemiological studies have failed to produce definitive evidence that exposure to ionizing radiation increases the risk of heritable genetic effects in the descendants of those exposed (ICRP 2007). Even the follow-up of more than 30,000 offspring of the Japanese atomic-bomb survivors who were conceived after the bombings has not provided clear evidence of an inherited effect from parental exposure. Nonetheless, large experiments involving laboratory animals, mainly mice, have produced unambiguous evidence that irradiation of parents does raise the risk of hereditary effects in offspring. The risk of radiation-induced hereditary effects in humans derived from this evidence suggests that this risk is much lower than the risk of cancer in the exposed individual.

The lens of the eye is sensitive to radiation-induced cataracts, and recent evidence indicates that the threshold for the production of cataracts, at around 500 mGy of low LET radiation, is much lower than the 5 Gy previously considered as a threshold dose (ICRP 2012). This evidence comes from the Japanese atomic-bomb survivors, the Chernobyl ‘liquidators’, and medical staff.

The embryo and foetus are sensitive to radiation-induced developmental (teratogenic) effects, such as, early in pregnancy, congenital malformations (although death may occur before birth defects become likely) (ICRP 2007). Severe mental retardation was found among Japanese atomic-bomb survivors exposed *in utero* to high doses during 8–15 weeks of gestation, and less so at 16–25 weeks, and lower doses may depress IQ.

An issue requiring resolution is whether low doses/dose-rates are capable of raising the risk of non-cancer somatic diseases, in particular diseases of the blood circulatory system, such as heart attack and stroke (ICRP 2012). It has been known for some time that high doses can lead to an excess risk of

these diseases, and this was attributed to tissue damage produced during such exposure, but epidemiological evidence is mounting for an effect at lower doses. However, a mechanism has yet to be identified, and the confounding effects of major (non-radiation) risk factors cannot yet be reliably eliminated as responsible for the association. Nonetheless, the potential risk of circulatory disease following low-level exposure to radiation is considered sufficiently important that significant research effort is being devoted to its investigation.

Policy and prevention (ionizing radiation)

The International Commission on Radiological Protection (ICRP), in its latest assessment of evidence provides detriment-adjusted nominal risk coefficients for all cancers combined: 5.49% Sv^{-1} for the whole population and 4.07% Sv^{-1} for the working population, for low doses/dose-rates of radiation (ICRP 2007). The detriment-adjusted nominal risk coefficients for hereditary effects are: 0.2% Sv^{-1} for the general population and 0.12% Sv^{-1} for a working population. Consequently, the aggregated detriment-adjusted nominal risk coefficients for stochastic effects following low-level exposure to radiation are 5.7% Sv^{-1} for a general population and 4.2% Sv^{-1} for a working population. These risk coefficients form the technical basis of the current framework of radiological protection recommended by the ICRP, and give rise to dose limits: for workers, the limit is an effective dose of 20 mSv per year averaged over a defined period of five years (with a maximum of 50 mSv in any one year), and for the general public the limit is an effective dose of 1 mSv in a year (although in special circumstances a higher dose could be received in any one year provided the annual average is 1 mSv over a 5-year period). These limits do not apply to medical or naturally occurring sources of exposure, although residential exposure to radon and its radioactive decay products in some areas of the world are assessed to produce a sufficiently high risk of lung cancer that remediation measures are required to reduce the exposure.

The three key principles of radiological protection remain: (1) the justification of activities that could cause or affect radiation exposures; (2) the optimization of protection in order to keep doses as low as reasonably achievable; and (3) the application of dose limits (ICRP 2007). The recommendations state:

No practice involving exposures to radiation should be adopted unless it produces sufficient benefit—to the exposed individuals or to society—to offset the detriment it causes.

In relation to any particular source within a practice, the magnitude of individual doses, the number of people exposed, and the likelihood of incurring exposures (where these are not certain to be received) should all be kept as low as reasonably achievable, economic and societal factors being taken into account.

The exposure of individuals resulting from the combination of all the relevant practices should be subject to dose limits, or to some control of risk in the case of potential exposures; hence, ensuring that no individual is exposed to radiation risks that are judged to be unacceptable from these practices in any normal circumstances. Dose (or risk) constraints are used to restrict to upper bounds the dose received (or potentially received) from a specific source.

Restrictions on effective dose sufficient to ensure the avoidance of deterministic effects in all body organs and tissues, and that limit the risk of stochastic effects to acceptable levels, are shown in Table 7.2.4.

Table 7.2.4 Recommended dose limits (ICRP 2007)

Type of limit	Occupational	Public
Effective dose	20 mSv per year, averaged over defined periods of 5 years, with a maximum of 50 mSv in any one year*	1 mSv in a year
Annual equivalent dose in		
Lens of the eye	20 mSv per year, averaged over defined periods of 5 years, with a maximum of 50 mSv in any one year	15 mSv
Skin	500 mSv	50 mSv
Hands and feet	500 mSv	-

* The basis for the control of the occupational exposure of women who are not pregnant is the same as that for men. However, once pregnancy has been declared, the embryo/foetus is protected—the effective dose limit for the embryo/foetus is 1 mSv.

Conclusions

The nature, frequency, and severity of adverse effects on human health caused by exposure to ionizing and non-ionizing radiation varies depending on the intensity and other exposure parameters, and is highly frequency-dependent. Potential effects range from rapidly fatal injuries to birth and hereditary defects, cancer, and other chronic diseases. Many effects occur only at high levels and are controlled or reduced by observing applicable exposure standards. In this chapter, our main emphasis is on exposures common in the everyday life and on long-term effects, which are typically of most concern to the public.

The IARC classified ionizing radiation and ultraviolet radiation as ‘known’ or Group 1 carcinogens, while extremely low frequency magnetic fields and radiofrequency fields have been classified as a ‘possible human carcinogen’, or a Group 2B, and static fields as well as extremely low frequency electric fields have been assigned Group 3 (not classifiable as to

carcinogenicity to humans). Intermediate frequencies and infrared radiation have not yet been classified as to their carcinogenic potential.

As it is not possible to eliminate exposure to ionizing radiation, these exposures are kept to a practical minimum. Most recommend avoiding high levels of solar UV exposure in order to facilitate the prevention of skin cancers. Because of the beneficial effects of solar UV exposure it is necessary to adopt a balanced set of recommendations regarding this exposure. For ELF magnetic fields, given exposure prevalence, considerable scientific uncertainty, and limited public health impact, no or very low-cost precautionary measures are justified. For RF, potential risk could affect a large number of people because of the ubiquitous nature of the exposure. Thus, given the important gaps in knowledge and availability of no- to low-cost measures, such as use of hands-free devices to reduce exposures from mobile phones, such measures can and should be adopted.

Rigorous studies capable of addressing knowledge gaps are urgently needed, particularly for rapidly growing technologies such as mobile phones, MRI exposures, IF antitheft, and device tagging, and modern magnetic levitation (maglev) systems.

ACKNOWLEDGEMENTS

We are grateful to Andrew Nguyen for his help in editing this chapter.

Occupational health

David Koh and Wee Hoe Gan

Introduction

The World Bank Group (2017) estimated the global labour force in 2017 at 3.449 billion, about 45% of the world's population. Females comprised 39.3% of the total labour force. In addition to workers engaged in hazardous industries, child labour, migrant workers, and those in vulnerable employment continue to be groups of concern when it comes protecting workers' health. Rising life expectancies and declining birth rates have led to population ageing globally, which will impact the demographic profile of the workforce. The average age of the labour force is projected to increase from nearly 40 in 2017, to 41 in 2030 (ILO 2018). While this may be small from a global perspective, the proportion of aged workers will increase, especially in Europe and East Asia. This will put pressure on countries and industries to help older workers adapt physically and psychosocially to changes in the work environment.

Occupational health is therefore a cornerstone to meet the challenges of the workforce now and in the future. The term 'occupational health', as defined by a joint committee of the World Health Organization (WHO) and the International Labour Organization (ILO), involves the 'promotion and maintenance of the highest degree of physical, mental and social wellbeing of workers in all occupations' (Forsmann 1983). This definition emphasizes the term health rather than disease, and further implies a multidisciplinary responsibility as well as a mechanism for the provision of health services for the working population. Occupational health seeks to not only maintain and promote workers' health and working capacity, it also extends to the improvement of working environment and work to be conducive to safety and health (Coppee 2011).

Occupational health practice encompasses the health protection, optimization, and management at the levels of the working population and individuals (Harber et al. 2010). For the former, the main components are the formulation of occupational health legislations and policies to protect the health of the workforce, the systemic reduction of risks from exposure to workplace hazards, and health promotion for those at work. Occupational health interventions at the individual level include primary prevention (e.g. occupational health training for workers, immunizations for healthcare providers), secondary prevention (e.g. pre-placement and periodic medical surveillance), and tertiary prevention (e.g. return-to-work assessments and programmes). In tertiary healthcare institutions, specialized clinical activities such as multidisciplinary management (e.g. occupational dermatology clinic jointly managed by occupational physicians and dermatologists), disability assessments, and acute management of occupational exposures (e.g. excessive mercury exposure) are undertaken (Barron et al. 2005).

Occupational health must be practised taking the context of the worker's job roles and environment. Both work and non-work environmental conditions can affect the health of the worker and in turn, his ability to undertake work safely and effectively. From the traditional ambit of industrial hygiene and ergonomics, the scope of occupational health practice must necessarily extend to include environmental health considerations and the holistic management of the workforce. Examples include hazardous waste management and disposal in a chemical plant, prevention of outbreaks of occupational infections in a healthcare facility, emergency preparedness and response (American College of Occupational and Environmental Health (ACOEM) 2010).

History and evolution

The Italian physician Bernardino Ramazzini (1633–1714) is often described as the 'Father of Occupational Medicine'. His publication, *De Morbis Artificum Diatriba*, is the seminal text in occupational medicine. Ramazzini stated that according to Hippocrates' teaching, 'When you come to a patient's house, you should ask him what sort of pain he has, what caused them, how many days he has been ill, whether the bowels are working and

what sort of food he eats' (Ramazzini 1713/1964). Following this citation, Ramazzini wrote: 'I may venture to add one more question: *What occupation does he follow?*' Ramazzini described many occupational illnesses that are still seen today, and the principles for their control.

The Industrial Revolution in the eighteenth century influenced the development of occupational health profoundly. Engineering and scientific innovations in the Western world, related to newly introduced industrial processes and the setting up of factories, led to dramatic social changes. Previously, work was done mainly by craftsmen in rural cottage industries. The Industrial Revolution resulted in work being carried out in factories in urban centres.

Effects were seen both within the community, as well as in the individual worker. Family life was disrupted, with men leaving their families and moving to work in new industrial areas. In these new areas, health and social problems emerged, for example, poor housing and sanitation, alcoholism, prostitution, and poverty. Inside factories, individuals were exposed to long hours of work, uncontrolled occupational hazards, and the risk of accidents. Child labour and apprenticeship of young children were common, and there was an absence of labour legislation.

The World Wars in the first half of the twentieth century further propelled our understanding of hazardous occupational exposures and diseases. Workers were affected with tetrachloroethylene (TCE) poisoning from applying TCE to aircraft wings, and trinitrotoluene poisoning from filling ammunition shells with little or no personal protection. Some of the phenomena seen in the Industrial Revolution are being replicated in the rapidly industrializing developing nations. Even in developed nations, similar problems are still encountered by migrant workers and other deprived sectors of the working population.

Occupational health legislation

Occupational health legislation in many countries is one of the most important measures to protect workers' health. For example, in the United States (US), the Occupational Safety and Health Act was passed by Congress in 1970. The United Kingdom (UK) Health and Safety at Work Act 1974 provided a broad legislative framework for the protection of

workers. The European Union (EU) adopted a policy in 1989 on the 'Fundamental Social Rights of Workers', emphasizing the need for safety and health protection in the workplace, improvements in living and working conditions, and provision of social protection for workers.

Internationally, there is growing recognition that a collective ownership is necessary for occupational health and safety. At the Sixtieth World Health Assembly, the WHO endorsed the global plan of action on workers' health (WHO 2007). This calls for, among other goals, national policy frameworks on workers' health, the protection and promotion of health at the workplace, and the improvement of access to occupational health services.

Disease burden and epidemiology

The ILO reported that in 2015, there were an estimated 2.78 million cases of deaths from occupational causes (Hamalainen et al. 2017). The majority (2.40 million) were due to fatal work-related illnesses, while the rest resulted from work-related accidents. On average, over 7,500 work-related deaths occur every day. About 31% of work-related mortality were due to circulatory diseases, 26% due to malignant neoplasms, 17% due to respiratory diseases, 14% due to occupational injuries, and 9% due to communicable diseases. Respiratory diseases now constitute the third most common cause of work-related mortality as a result of the formal recognition of occupational exposures to a multitude of vapours, gases, dusts, and fumes as an important cause of chronic obstructive pulmonary disease (Collegium Ramazzini 2016).

Approximately 5–7% of global fatalities are thought to be attributable to work-related illnesses and occupational injuries (Lopez and Mathers 2006). The population attributable fraction (PAF), or proportion of a disease that would be avoided in the absence of the risk factor under consideration, is often used to estimate the burden of occupational diseases. While there are several methods to estimate PAF, a commonly used approach is to multiply the relative risk from occupational exposure with the proportion exposed in the population of interest (Steenland and Armstrong 2006). The PAF should be interpreted in context because assumptions may be applied—an example is the period of cancer latency, which affect the determination of the

appropriate occupational exposure period to the carcinogen of interest (Ruston 2017).

In terms of global morbidity, an estimated 37% of back pain, 16% of hearing loss, 13% of chronic obstructive pulmonary diseases, 11% of asthma, 10% of injuries, 10% of lung cancers, and 2% of leukaemia are related to work (Concha-Barrientos et al. 2004).

It is generally accepted that occupational and work-related illnesses are underreported. Occupational epidemiological studies are also often subjected to a selection bias known such as the healthy worker effect (HWE). HWE describes the better health status of workers relative to the general population and is often ascribed to the exclusion of unhealthy workers at employment and the study of active workers (Li and Sung 1999). Several methods have been described to minimize HWE, such as choosing active workers from another industry as the reference group instead of the general population. There is no standard solution and the approach needs to be customized for individual studies.

Over 100 occupational diseases have been classified according to the tenth revision of the International Classification of Diseases and Related Health Problems (ICD-10), and the list is expected to grow in ICD-11. To determine which occupational exposure leads the development of a particular occupational health condition may not be straightforward, given the multifactorial and dynamic nature of exposure-health interface in many workplaces. Recent occupational epidemiological research to map multiple occupational exposures with disease outcomes through novel models will allow better characterization and provide a clearer understanding of the multidimensional interactions between occupational hazards and ill-health (Bosson-Rieutort et al. 2018).

Estimates of costs and economic loss

The economic cost associated with work-related disease ranges from 1.8 to 6.0% of a country's gross domestic product (average 4%) (Takala et al. 2014). Occupational injuries and illnesses account for about US$250 billion annually to the overall national costs of all diseases, injuries, and deaths in the US (Leigh 2011). The UK estimated that the costs of workplace injuries and new cases of work-related ill-health from 2015 to 2016 to be £14.9 billion (Health and Safety Executive (HSE) 2017a).

The main contributors are direct costs for medical care, rehabilitation, and compensation; indirect costs related to lost opportunities for the injured worker and employer comprising salary costs, administrative costs, and productivity losses; and human costs as a result of the change in the quality of life of the worker and those around him (IRSST 2013).

Major types of occupational diseases and injury

Occupational illness can affect virtually every organ system. Occupational diseases of the lung and skin are common since these organs have substantial surface areas in direct contact with toxic substances. Noise-induced hearing loss and musculoskeletal disorders are among the most common disorders arising from physical factors in the workplace. Occupational cancer is a major concern because of its high mortality. More attention is now being channelled to the domains of psychosocial stress at work; occupational infections (especially with the emergence of multidrug-resistant organisms); and health hazards related to new agents such as nanomaterials; and maturing technologies such as the knowledge industry.

Occupational lung diseases

The respiratory system is an easily accessible target organ for airborne toxic agents. Major categories of occupational lung disease include the pneumoconioses (‘dust diseases’ of the lungs), lung cancer, occupational asthma, chronic bronchitis and other effects of respiratory irritants, and occupational pulmonary infections.

Silicosis is the most common form of pneumoconiosis worldwide. Exposure to silica occurs in a wide variety of occupations such as sandblasters, miners, millers, pottery workers, foundry workers, and workers using abrasives. Approximately 2.3 million workers in the US are exposed to respirable crystalline silica (RCS) at the workplace (Centers for Disease Control and Prevention 2017). The International Agency for Research on Cancer (IARC) has classified crystalline silica as a known human carcinogen (IARC 1997).

Asbestos is another important cause of lung diseases that include mesothelioma, lung cancer, and asbestosis (a form of progressive pulmonary fibrosis). There are different forms of this group of naturally

occurring fibrous minerals, with the main ones being chrysotile (white asbestos) and crocidolite (blue asbestos). All forms are carcinogenic. It is estimated that 125 million people in the world are exposed to asbestos at the workplace (WHO 2017a). Asbestos is responsible for over 100,000 deaths per year worldwide (Takala 2003), with an estimated 38,400 deaths annually due to mesothelioma (Odgerel et al. 2017). Given the long latency, the future burden of mortality resulting from asbestos will be substantial even if all future exposure were to be eliminated completely.

Work-related asthma (WRA) comprises occupational asthma and work-exacerbated asthma (WEA, i.e. asthma not caused by, but rather worsened by an occupational exposure). At least 15% of adult asthma is thought to be work-related (Tario and Lemiere 2014), and WEA may occur in up to 25% of working persons with asthma (Henneberger et al. 2011). WRA may be caused by occupational allergens (such as inhalation of hay dust in farmers) or irritants (cleaning agents is a common group of irritants). Unlike non-WRA, the optimal management of WRA is primary prevention by eliminating or reducing occupational exposures. If the socioeconomic situation precludes total avoidance, work re-entry programmes may enable sustained employment after diagnosis (Malo et al. 2015). Prevalence studies of occupational asthma usually underestimate the number of affected workers because workers tend to quit jobs where they suffer such symptoms, although their asthma symptoms and signs may continue even after leaving work.

Many vapours, gases, dusts, and fumes (VGDF), such as hydrogen chloride, organic solvents, and welding fumes, can cause irritant effects to the respiratory tract. Increasingly, occupational exposure to VGDF is also shown to be associated with chronic obstructive pulmonary disease (COPD). For example, the Swedish CArdioPulmonary BioImage Study (SCAPIS) demonstrated that the PAF for occupational exposure to VGDF was 0.37 for COPD and 0.23 for emphysema (Toren et al. 2017). It is important that the occupational risk of VGDF exposure be fully appreciated so that adequate preventive measures can be put in place for workers' protection.

Occupational cancers

Occupational carcinogens include chemical substances, for example, benzene and asbestos; physical hazards, for example, ionizing radiation;

and biological hazards, for example, viruses. It is estimated that approximately 16 million workers in the EU are exposed to carcinogens at work. The most common cancers due to these workplace exposures are cancers of the lung, bladder, skin, and liver.

Occupational cancer accounts for about 4–20% of all cancers in developed countries. Variability in the estimates arises from differences in data sets used and assumptions applied. In the UK, 8.2% and 2.3% of mortality from cancers in males and females, respectively were occupation-related, giving an overall PAF of 5.3% (Rushton et al. 2012). Due to the complex interactions between exposure and causation in occupational cancers, the probability of causation model has, to date, been successfully applied only to occupational cancers after ionizing radiation exposure (Niu and Deboodt 2010).

Occupational and work-related skin diseases

Skin disorders are among the most commonly reported occupational diseases. Similar to many occupational disease classifications, the main difference between work-related skin diseases (WRSD) and occupational skin diseases (OSD) is whether the occupational exposure is assessed to be partially or fully attributed to the development of the skin disorder. In Europe, the annual incidence of WRSD is estimated at 0.5–1 per 1,000 workers (Mahler 2017) with the most common condition being contact dermatitis. Although skin disorders are relatively easily diagnosed, OSD are believed to be under-reported, so that the actual rate is many times higher than officially reported (European Agency for Safety and Health at Work 2008).

WRSD/OSD are unevenly distributed between industries. Workers in agriculture, forestry, fishing, manufacturing e.g. metal workers, and some service industries, e.g. florists, hairdressers, and barbers, have a greater risk of developing WRSD/OSD. This is likely to be due to their exposure to a wider range of substances known to be irritants or allergens. With greater recognition and understanding of the role of occupational factors in skin diseases (e.g. occupational UV-induced skin cancer), there will be a revision in the Occupational Skin Diseases section of ICD-11 to provide a more comprehensive framework and facilitate precise definition and classification (Alfonso et al. 2017).

Occupational reproductive disorders

The overall contribution of occupational exposures to reproductive disorders is not well characterized because of limited research in this area. Few studies are available, especially on physical and biological agents that may affect fertility and pregnancy outcomes in humans.

Occupational exposure to chemical agents such as lead (Pb) and the pesticide dibromochloropropane (DBCP) have been documented to cause testicular effects with resultant reduction in sperm count. Pb can also cross the placenta in pregnant women to affect the developing foetus. Other substances associated with documented adverse reproductive outcomes include metal compounds (e.g. methyl mercury), solvents (e.g. carbon disulphide), oestrogenic agents, anaesthetic gases, antineoplastic drugs, carbon monoxide, ethylene oxide, ethylene glycol ethers, polychlorinated biphenyls, and physical agents (e.g. ionizing radiation).

Occupational exposures can cause a wide range of reproductive disorders in both males and females (Kumar 2004; Jensen et al. 2006). Effects in males include reduced sperm count, aberrant sperm shape, altered sperm function; and lowered hormone levels or libido. Exposures in females may cause menstrual cycle irregularities, infertility, chromosomal aberrations, reduced breast milk production, early onset of menopause, and suppressed libido.

Reproductive disorders also include adverse effects on the offspring of the exposed worker (Burdorf et al. 2011). Potential foetal and developmental effects from maternal exposures include preterm delivery, foetal loss, prenatal death, low birth weight, altered sex ratio of live births, congenital malformations, childhood malignancies, and neurobehavioral disorders in the offspring.

Occupational noise-induced hearing loss

Exposure to excessive noise is a major occupational hazard in many industries. In the US, about 22 million workers are exposed to hazardous noise levels at work (NIOSH 2018). An estimated 16% of disabling hearing loss in adults worldwide is attributed to occupational noise (Nelson et al. 2005). In most developing countries, noise-induced hearing loss (NIHL) is one of the most commonly reported occupational disorders.

Workers in manufacturing, mining, construction, transportation, agriculture, and the military are at high risk for NIHL. There is also an association between maternal occupational noise exposure and hearing dysfunction in the offspring (Selander et al. 2016). A Cochrane Review (Tikka et al. 2017) showed varying effectiveness of legislation, engineering control measures, and use of hearing protection devices in preventing NIHL. Nevertheless, the implementation of these measures has led to a systematic framework of noise hazard reduction for the at-risk industries.

Occupational infections

Healthcare is one of several sectors whose professionals are at risk of occupational infections. In addition to blood-borne diseases such as hepatitis B, hepatitis C, and HIV, airborne and droplet-borne infections such as measles, varicella, tuberculosis, and pertussis may also be transmitted from patients to healthcare workers (HCW). Many of these infections are preventable with immunizations. It has been estimated that 9–42 HCW per million die annually from occupational infections (Sepkowitz and Eisenberg 2005).

The incidence rate of sharps injuries in HCW is about 3.7 per 100 HCW per year (Elseviers 2014), though it is known to be underreported (Elder and Paterson 2006). Needlestick injuries accounted for about 40% of hepatitis B and hepatitis C infections, and 4.4% of HIV infections in HCW (Pruss-Ustun et al. 2005). However, with the stricter implementation of universal precautions, adherence to standard operating procedures, introduction of surgical and phlebotomy devices with safety features, and availability of effective post-exposure prophylaxis for occupational infections in high risk cases, a gradual reduction in the incidence of occupational transmission is achievable.

Transmission of *M. tuberculosis* is a recognized risk in healthcare facilities, and multidrug-resistant tuberculosis and extensively drug-resistant tuberculosis have re-emerged as a major occupational and public health problem. The risk of latent tuberculosis infection and tuberculosis disease is considered to be higher in HCW compared to the corresponding local communities (Baussano et al. 2011).

Emerging infectious diseases also pose a risk to HCW. Two examples are the Severe Acute Respiratory Syndrome (SARS) and the Middle East respiratory syndrome (MERS), both of which are caused by novel

coronaviruses. In the 2003 worldwide outbreak of SARS, 20% of patients were HCW (Koh et al. 2003). HCW have also been shown to be the propagating vehicles for healthcare facility outbreaks (Alfaraj et al. 2018).

Other workers besides HCW may also at risk for occupational infections. Some of the infections result directly from the work, while others are indirectly related to work. Examples include vector-borne diseases, such as malaria, dengue haemorrhagic fever, Lyme disease, and anthrax; water and food-borne diseases resulting from poor sanitation and inadequate potable water, such as cholera and typhoid; and zoonoses among veterinarians, farmers, agricultural and forestry workers, such as leptospirosis and rabies.

Occupational traumatic injuries

These injuries include such events as amputations, fractures, severe lacerations, eye injuries, and burns. In 2014, approximately 374 million workers sustained non-fatal occupational injuries that resulted in an absence of 4 days or more from work (Hamalainen P et al. 2017). This translates to an annual accident incidence of 11,096 per 100,000 workers. In the UK, statistics of non-fatal injuries showed that the top 5 causes are—slip, trip or fall on the same level (29%), lifting/handling (22%), struck by object (10%), fall from height (7%), and acts of violence (7%) (HSE 2017b).

Work-related diseases

Work-related diseases are diseases in which occurrence may be associated with workplace factors, but these need not be the only risk factor in each case. They occur more commonly than pure ‘occupational diseases’. The term is also used to refer to aggravation of a pre-existing medical condition by workplace factors. While prevention of occupational diseases is possible by the elimination of the workplace hazard, work-related diseases cannot be entirely prevented by only addressing occupational hazards. Common work-related diseases include hypertension, ischaemic heart disease, psychosomatic illnesses, musculoskeletal disorders, and non-specific respiratory disease. Two examples are given next.

Work-related musculoskeletal disorders

Acute and chronic work-related musculoskeletal disorders (WRMSD) are a major cause of morbidity affecting workers. The term encompasses a range of conditions from back pain, upper and lower limb disorders, neck and shoulder symptoms, hand–arm vibration syndrome (HAVS), carpal tunnel syndrome, repetitive strain injury, and other effects on the musculoskeletal system. There is substantive evidence to support the aetiologic importance of physical risk factors, including rapid work pace and repetitive motion, forceful exertions, non-neutral body postures, and vibration (Punnett 2014). Psychosocial factors such as high job demands, lack of job control, and monotonous work have additionally been shown to be associated with increased WRMSD risk.

In the UK, more than 0.5 million workers suffer from new or longstanding WRMSD between 2016 and 2017, resulting in a loss of 8.9 million working days (HSE 2017c). In the US, WRMSD accounted for 34% of all lost workdays, and one out of every three dollars spent on workers' compensation (Occupational Safety and Health Administration (OSHA) 2014). The implementation of ergonomic measures, and simple interventions such as stretching exercises may be effective in preventing WRMSD (Podniece et al. 2008; Aje et al. 2018).

A common WRMSD is low back pain (LBP). LBP from occupational ergonomic factors accounts for about one-third of all disabilities with occupational risk factors (Driscoll et al. 2014). Given the high prevalence of back pain in the general population and its episodic nature, it is not always easy to determine the work-relatedness of this condition. While there are many studies demonstrating the association between work-related factors and the development of LBP, a recent longitudinal study showed that early exposure to heavy physical workload is associated with more than 30% risk of local and radiating LBP after a follow-up of 21 years (Lallukka et al. 2017). This highlights the importance of primary prevention even in younger workers when they enter the labour market.

Stress-related ill-health

Work-related stress has been defined as the 'harmful physical and emotional responses that occur when the requirements of the job do not match the capabilities, resources or needs of the worker' (NIOSH 1999). Over the past half century, globalization and rapid technological advancements introduced significant changes to the workplace. New forms of work organization and

employment patterns (e.g. more temporary and independent contracting) bring about job flexibility, yet at the same time result in lower control and a heightened sense of job insecurity. The fast pace of technological renewals enhances work efficiency, but also requires workers to constantly keep up with changes. Greater connectivity through the internet has blurred the boundary between work and personal life. Past European Working Conditions Surveys gave a prevalence of between 11.8% and 27.0% of work-related stress in the UK working population (Houdmont et al. 2010).

The clinical manifestations of occupational stress are indistinguishable from non-occupational stress. It can present as emotional lability, anxiety, depression, insomnia, and even attempts at suicide. Adverse health outcomes of job stress are wide ranging, from increased risk of cardiovascular disease, musculoskeletal symptoms, impaired immune function, and gastrointestinal disorders (e.g. peptic ulcers and irritable bowel syndrome). The varying rates of coronary heart disease across occupations, and the link between work-related psychosocial factors and WRMSD support the role of work conditions in work-related stress (ILO 2016a). In extreme situations, work-related stress may result in *karoshi* (death by cerebrovascular and cardiovascular diseases due to overwork) and *karojisatsu* (suicide due to overwork) (Yamauchi et al. 2017).

Under-recognition of occupational ill-health

Many countries maintain occupational disease registries. However, the lack of internationally agreed reporting standards and, in some cases, tedious notification processes result in the underestimation of the prevalence of some of the occupational diseases under surveillance (Somayeh et al. 2017). It is generally accepted that occupational and work-related diseases are underdiagnosed. One explanation for this is the inherent difficulty in establishing cause-and-effect relationships for occupational diseases. The link between occupation and disease may sometimes be unclear, because most occupational diseases are not distinct clinically and pathologically from diseases associated with non-occupational aetiologies. For example, skin cancer caused by polycyclic aromatic hydrocarbons is similar in appearance to that caused by excessive exposure to sunlight. Similarly, solvent-induced encephalopathy may easily be confused with effects of advancing age. Only for a very limited number of diseases, for example,

mesothelioma (caused by asbestos), and angiosarcoma of the liver (caused by vinyl chloride monomer) are the causal association between occupational exposure and disease readily established based on strong epidemiological evidence and a good occupational history documenting exposure.

The long latency which typically elapses between occupational exposure and onset of illness is a second factor which may obscure the occupational aetiology. For example, occupational cancers rarely appear within 10 or even 20 years of first exposure to a carcinogen. Similarly, chronic solvent-induced encephalopathy may develop insidiously only after years of exposure.

Lack of a good understanding among health practitioners about the hazards found at work is a third cause of underestimation of occupational disease, reflecting the fact that most physicians are not adequately trained to suspect work as a cause of disease (Baillargeon et al. 2011). Technological evolutions and changes in employment patterns lead to new occupational diseases, further compounding this knowledge deficit. With competing demands for time in the medical curriculum from an increasing number of disciplines and subject areas, most medical schools now only allocate limited time to teaching medical students to take a proper occupational history, to recognize symptoms of common industrial toxins, or to recall known associations between occupational exposures and disease.

Compounding a lack of medical awareness is the limited ability of many workers to provide an accurate report of their exposures. Workers may have had multiple toxic exposures in a variety of jobs over a working lifetime. In many developing countries today, there is still no formal requirement to inform workers of the hazard of the materials with which they work. In many instances, a patient may not know or may not be able to remember all his or her past occupational exposures.

Finally, given the potential financial liability associated with the finding that a disease is of occupational origin, employers may be reluctant to recognize the work-relatedness of a disorder, especially in cases where personal habits or non-occupational pursuits are possible contributory factors. Since employers are often in the best position to recognize causal associations between workplace exposures and disease, this conflict of interest represents an obstacle to obtaining accurate estimates of the burden of occupational illness.

Many of the occupational hazards today are still not fully evaluated for their potential toxicities. While it is another reason for the under-recognition of occupational diseases, there is a concerted effort globally to improve this through better classification and communication of the risk to workers.

Special populations of workers

Workplace hazards affect some worker populations disproportionately, for example, child labourers, women employees, and impaired workers. These populations are especially vulnerable because of the interaction between their work roles and broader roles in society, as well as by their particular exposures in the workplace.

Child labour

The ILO estimates 218 million children between five and 17 years are in employment globally, of whom 152 million are victims of child labour. Of the latter group, 73 million are engaged in hazardous work, concentrated primarily in agriculture (e.g. fishing, forestry, livestock herding). About 22,000 children are killed at work every year (International Programme on the Elimination of Child Labour (IPEC) 2017).

Children are vulnerable to exploitation in the workplace and may be denied basic human rights, such as decent wages or access to education. Children in hazardous occupations are at greater risk of suffering ill effects than adult workers. They may have greater exposure to hazards than adult workers in the same occupation because children tend to be given the most menial jobs, which can involve higher exposures to toxic substances. Children are more susceptible to the same hazards faced by adult workers because they differ from adults in their physical, physiological, and psychological characteristics. Children using hand tools designed for adults run a higher risk of fatigue and injury. Personal protective equipment (PPE) designed for adults do not fit children, and therefore do not provide adequate protection. Furthermore, children may not be as aware as adults of workplace dangers, or as knowledgeable of precautions to be taken at work. Children are also more vulnerable to psychological and physical abuse than are adults and suffer deeper psychological damage when they are denigrated or bullied.

In a study of more than 42,000 child labourers in Bangladesh, the incidence of injury and death among child labourers was 24 per 100,000 children-years (Dalal et al. 2016). The top three causes of injury were cuts/open wounds, abrasions/lacerations, and sprains; and the corresponding top causes of death were suicide, road traffic injuries, and electrocution. Child labour not only deprives children of education and training for a better future, it also perpetuates poverty and impacts countries' economies through loss of competitiveness and productivity. The International Programme on the Elimination of Child Labour (IPEC), established under ILO, works with member States and partners to encourage the withdrawal of children from child labour by providing them with education, and assisting their families with skills training and employment.

Women workers

In 2015, nearly 1.3 billion women were in the workforce compared to almost 2 billion men. As a global average, the female employment-to-population ratio was 0.46, whereas the corresponding male ratio was 0.72 (ILO 2016b).

There is significant interplay between women's roles in society, socioeconomic condition, and occupation. Women's roles in traditional societies are defined in relation to childbearing and upbringing of children, and responsibility for the care and comfort of the family. Paid employment of women has increased in most countries, but this has led to a conflict between the necessity to be at work and women's traditional home and family responsibilities. In many societies, early marriage, repeated pregnancies, large families, low educational status, and poverty all disproportionately impact on women workers. Even today, international objectives for women's health, such as the Millennium Development Goals, are focussed on maternal-child health rather than advancing women's intrinsic health (Mohindra 2016).

Employment of women in most societies is characterized by occupational segregation, underemployment (often involved in doing seasonal and part-time work below their level of education), and barriers to advancement. Occupational segregation means that women tend to be clustered into a small number of occupations while being under-represented in most others. Women in developing countries tend to be employed in sectors such as

agriculture, textiles and clothing, food processing, and social services. Compared with men, women work for smaller industries or organizations, and have less opportunity for work control. Women are more likely to work in the informal sector, in specific types of informal work such as domestic work, street vending, and sex work, with their accompanying low social status and lack of legislative protection. Gender differences are also observed in the rates of occupational injuries and illnesses, including the higher rates of mental disorders in females based on studies of workers' compensation claims (Berecki-Gisolf et al. 2016).

Increasing recognition of the importance of gender differences towards risks at work has led to gender mainstreaming in occupational health and safety (OHS). This refers to the systematic consideration of the differences between the conditions, situations and needs of female and male workers, and integrating these into the design, implementation, monitoring, and evaluation of OHS (European Agency for Safety and Health at Work 2014).

Disabled workers

A large proportion of individuals with disabilities are in the working age group, and they are able to make constructive contributions in the workplace despite physical impairment. Legislation in some countries, such as UK's Equality Act 2010, prohibits employers from discriminating against individuals with disabilities, and encourages employers to make reasonable accommodation for those with a known impairment (HSE 2015). The Americans with Disabilities Act limits employers from asking job applicants to answer medical questions, take a medical examination, or identify a disability (US Equal Employment Opportunity Commission (EEOC) 2008).

France and Germany impose quotas on enterprises to employ a certain percentage of disabled people. India and Japan use employment promotion measures to ensure workplace accessibility and provide employment services in the form of job placement agencies. Singapore provides tax reductions as a financial incentive to compensate employers for any financial burden resulting from the employment of disabled people.

Reasonable accommodations are changes made to the work environment, job responsibilities, or conditions of work that provide opportunities for workers with special needs to perform essential job functions. The aim is to

ensure that, as far as reasonably practicable, a disabled person has the same access to everything that is involved in performing and keeping a job as a non-disabled person. These measures may include technical assistance devices; customization, including PPE and clothing; and changes to processes, location, or timing for essential job functions. Many studies have demonstrated benefits of hiring people with disabilities, including improvements in profitability (e.g. cost-effectiveness); staff retention, reliability, and punctuality; employee loyalty; company image; competitive advantage (e.g. diverse customer pool, innovation); and inclusive work culture (Lindsay et al. 2018).

Migrant workers

Migrant workers refer to all international migrants who are currently employed, or are unemployed and seeking employment in their present country of residence. The ILO estimates that there are 150.3 million migrant workers globally (ILO 2015). This forms 3.9% of the total global population and 4.4% of the global workforce. The majority of migrant workers are in the services (domestic work, food services, administrative work) sector. The other sectors significantly represented include manufacturing, construction, and agriculture.

Migrant workers are a particularly vulnerable population. Many of them perform what are known as 3-D (dirty, dangerous, and demanding) jobs (Moyce and Schenker 2018). They may be affected by poor nutrition and endemic diseases, often have lower educational backgrounds, and are inadequately trained to deal with potential work hazards. Many face additional obstacles because they do not speak the language of the host country adequately. They are often not familiar with local health and safety practices and regulations. The accommodation available for them can be temporary and often crowded with limited shared facilities, and with restricted access to medical care and other social services. Migrant workers may encounter racism, xenophobia, and exploitation because they do not have full legal status or awareness of their rights in the host country (Holmes 2006). A review of fatal occupational injuries in the US from 2003 to 2010 found a risk difference of 15% increase in relative hazard for immigrant workers compared to their native counterparts (Byler and Robinson 2018).

Shift workers

Shift work can take the form of fixed shifts, where workers constantly work the same shift period; or rotating shifts, where workers' shift periods vary over time. It is estimated that in the EU, 17% of workers are engaged in shift work (ILO 2011).

Apart from sleep deficits and suboptimal work performance, shift work has also been associated with adverse effects on psychological health (e.g. anxiety and depression), gastrointestinal disorders (e.g. peptic ulcer disease), metabolic disorders (e.g. obesity and impaired glucose tolerance), cardiovascular diseases, reproductive disorders (e.g. preterm birth), and cancer (especially breast cancer in female shift workers) (Costa 2010). The IARC classifies shift work as a Group 2A carcinogen, defining it as 'probably carcinogenic to humans'.

Shift work-related ill-health may also increase with time of 'exposure'. A study found that after the first five years of shift work, the risk of cardiovascular events increases by 7.1% for every additional five years of exposure (Torquati et al. 2018). Given the complex and multifaceted interactions between shift work and health, it is important to minimize downstream consequences for susceptible workers through health surveillance, education, and proper organization of shift schedules.

Total workplace safety and health

Work as a social determinant of health has been extensively researched. It is recognized that workload, duration, intensity, psychological stress, access to workplace health promotion resources, and other occupational-related factors have an impact on well-being. There is no unified definition of well-being. The concept of well-being encompasses the presence of positive emotions and moods, engaging activities and work, fulfilment, and positive functioning (CDC 2016). By integrating physical health and well-being into a multidimensional indicator, it provides a more holistic approach to the understanding of occupational and work-related diseases and, in turn, their prevention and management.

Well-being, alongside safety and physical health, is an important outcome in occupational health and contributes to the changing paradigm of a new total workplace safety and health model. This model recognizes that

in addition to addressing workplace safety issues, good workplace health (physical and psychosocial health) is equally important because it affects the worker's overall well-being and therefore, his work capacity, and the overall performance of the organization. A central concept in Total Workplace Safety and Health is the protection and promotion of the health, safety, and well-being of all workers and the sustainability of the workplace (Workplace Safety and Health Council 2017).

To this end, individual risk factors, such as worker's health and fitness, are taken into consideration in risk assessment. By the corollary, integrating programmes that control such risks at the workplace, including workplace health promotion and workers' chronic disease management, can address risks that impact individual performance, organizational productivity, workplace accidents, and sickness absenteeism.

There are ample justifications for this integrated approach. Epidemiological studies show the following key findings, namely that occupational exposures and risk factors for chronic diseases may have synergistic adverse health effects on workers; workers with high risk for hazardous workplace exposures often have more risk factors for chronic diseases; and integration of the management of occupational safety and health with health promotion may increase worker participation and benefit the overall work environment (NIOSH 2012).

An illustration of this integrated approach to occupational health is the Total Worker Health® (TWH®) launched by the US' National Institute for Occupational Safety and Health (NIOSH) in 2011. TWH® is defined as policies, programmes, and practices that integrate protection from work-related safety and health hazards with promotion of injury and illness prevention efforts to advance worker well-being (NIOSH 2017). There are many domains in TWH®, which include control of work hazards and exposures (e.g. risk assessment and management); work organization (e.g. shift work, fatigue and stress prevention); support for built environments (e.g. health air quality, access to healthy and affordable food options); employment patterns (e.g. contract work, financial and job security); work policies (e.g. promotion of productive ageing, return to work); compensation and benefits (e.g. chronic disease management, work injury compensation); and leadership (e.g. supportive leadership, employee engagement, provision of meaningful work). These domains complement and mutually reinforce to not only protect workers from hazards, but also to

advance their health and well-being by targeting the conditions of work. A systematic review of TWH® interventions (Anger et al. 2015) demonstrated improved risk factors for injuries (e.g. self-efficacy towards safety) and chronic diseases (e.g. exercise, dietary habits, and measurable indicators such as lipid profile, blood pressure, and body mass index).

Return on investment may be significant. The introduction of the Promoting Healthy Lifestyle: Alternative Models' Effects (PHLAME) wellness programme in fire departments resulted in significantly lower work compensation claims and medical costs compared to fire departments without similar programmes, yielding an average cost saving per firefighter of $4.60 for every $1 invested in the programme (Kuehl et al. 2013). Apart from cost considerations for employers, Total Workplace Safety and Health approaches also complement broader public health outcomes in reducing at-risk health behaviours and the burden of chronic diseases. Interventions from such integrated programmes have been shown to reduce sedentary behaviour and tobacco use in workers (Feltner et al. 2016).

Occupational risk assessment

In occupational health practice, an understanding of the difference between the terms 'hazard' and 'risk' is essential.

Hazard refers to a substance, agent, or physical situation with a potential for harm in terms of injury or ill-health, damage to property, damage to the environment, or a combination of these. Hazards can be physical, chemical, biological, ergonomic, or psychosocial in nature. Physical hazards include exposure to extremes of temperature, light, noise, vibration, electricity, and radiation. Chemical hazards cover a range of organic (aliphatic or aromatic) and inorganic chemicals. Biological hazards are those due to infectious organisms (e.g. viruses, bacteria, rickettsia), and also prions and proteins. Ergonomic and mechanical hazards result from poor design of workstations and disorganized systems of work, and psychosocial hazards are those that contribute to and cause workplace stress. Hazard identification is the process of recognizing that a hazard exists and defining its characteristics.

Risk relates to the likelihood of the harm or undesired event occurring, and the consequences of its occurrence. It is the probability that the substance or agent will cause adverse effects under the conditions of use

and/or exposure, and the possible extent of harm. It is thus a function of both exposure to the hazard and the likelihood of effects on health from the hazard. Extent of risk covers the population that might be affected by the risk, the numbers exposed, and the consequences.

Assessing risk

Risk assessment is the process of estimating the magnitude of risk and deciding if the risk is tolerable or acceptable. A tolerable risk may not always be acceptable. It merely refers to a willingness to live with a risk to secure certain benefits, and in the confidence that the risk is being properly controlled. The levels of tolerability of risk are different for different countries, and in different working populations and the general public. The views on tolerability depend to a large extent on the populations that might be affected by the risk.

Risk assessment and risk management must take into account both routine and non-routine activities and conditions, including foreseeable emergency situations. Hazards that are intrinsic to these situations or generated by such activities should be recognized. Exposed people should be identified, including non-employees and those who are susceptible and therefore at higher risk because of illness or other medical conditions. Existing control measures, if any, need to be evaluated.

The health risks from the hazards should be determined and assessed, and a decision made on whether the risk is acceptable or tolerable. Unacceptable risks have to be eliminated or reduced with new or improved control measures, and their effectiveness monitored. Such a process requires a team effort, involving the workers themselves as well as personnel with the relevant expertise. It is important to inform workers of the hazards, risks, and appropriate measures that have been and can be taken to protect them.

The steps for risk assessment for chemical, biological, ergonomic, and psychosocial hazards may differ. The assessments for chemical or physical exposures are generally more objective and precise than the assessment for psychological stressors. As an example, an initial assessment for a chemical exposure might include the following steps:

List substances in the area to be assessed.
Determine which substances are actually used, and in what quantities, and the frequency and duration of use.
Evaluate workers' concerns.
Assess the tasks of workers, their exposure, and methods of handling.
Obtain suppliers' safety data sheets.
Evaluate safety data sheets.
Inspect places where the substances are handled.
Evaluate method(s) of control.
Perform environmental monitoring for the chemical if required.
Decide on acceptability or tolerability of risk, and if further control measures are needed.

The assessment of psychosocial factors at work is more complex. It may include the evaluation of organizational dysfunction, work conditions, as well as a study of indicators such as sickness absence, staff turnover, and measurement of stress-related illness among employees. Possible work stressors are poor design of tasks, aggressive management style, inadequate interpersonal relationships, unclear work roles, limited career prospects, and adverse workplace environmental conditions. The extent of work stress can be assessed by use of validated questionnaires administered to staff; for example, the General Health Questionnaire (Jackson 2007) or the NIOSH Generic Job Stress Questionnaire (NIOSH 2008).

Assessing exposure

Environmental monitoring

Environmental or ambient monitoring in the workplace is undertaken to measure external exposure to harmful agents. The monitoring is to ensure that exposure is kept within 'permissible levels' so as to prevent the occurrence of disease. The concept of permissible levels assumes that for each substance, there is a level of exposure at or below which the exposed worker does not suffer any health impairment.

Permissible levels or occupational exposure limits are standards that have been set for physical, chemical, and biological hazards in workplaces. There are variations in permissible levels or exposure limits from different

countries and different agencies. Much depends on factors such as the philosophy and rationale for the standards, the process of standard setting, nomenclature, and applicability, and whether economic considerations and technical feasibility are taken into account. For example, threshold limit values (TLVs) for chemical substances and physical agents are set and reviewed annually by the American Conference of Governmental Industrial Hygienists (ACGIH). They are derived using information from industrial experience, as well as studies in both animal and human populations. These standards are adopted by many countries, especially those without their own national occupational exposure standard setting mechanism. The US also has recommended exposure limits (RELs) produced by NIOSH, and permissible exposure limits (PELs) from the OSHA. The UK has Workplace Exposure Limits (WELs), and in Germany there are two groups of OELs: (1) technical guidance concentrations (TRKs), and (2) maximum concentration for a chemical substance in the workplace (MAK).

Permissible levels have their limitations. For example, a ‘safe’ level of exposure can be difficult to determine for agents such as allergens and carcinogens. As such, every effort must be made to keep exposure levels as low as reasonably practicable and the permissible level is then a level above which exposure must not occur. This level may be mandated by legislation. Concerns regarding health risks have arisen from substances assumed previously to be safe, for example, glycol ethers in the electronic industry associated with the risk of spontaneous abortions. Standards that are set for an 8-hour working day would not be applicable for a 12-hour work shift. Furthermore, exposure to several hazards simultaneously does occur. In such situations, there can be possible synergistic or additive effects. This would then require more stringent control of each individual hazard.

The methods for environmental monitoring require choice of the correct collecting devices, sampling strategy, and analysis of the collected samples in accredited laboratories. Variations in age, gender, pre-existing disease, genetic makeup, and social habits, for example, smoking, influence individual susceptibility and have to be considered in applying the findings from exposure assessment to the exposed population. Despite these limitations, sensible use of environmental standards can often result in practical control of many common workplace hazards so that the majority of workers are protected.

Biological monitoring

Biological monitoring of workers refers to the measurement and assessment of workplace agents or their metabolites either in tissues, secreta, excreta, expired air, or any combinations of these to evaluate exposure and health risk. The specific chemical or its breakdown product can be measured to detect the total body burden of the substance. The method of measurement of these substances must be validated and there should be a means to interpret the results obtained in terms of the extent of exposure, and risk to health.

Biological monitoring and environmental monitoring complement each other in the assessment of health risk in the exposed worker. One major feature of biological, as compared to environmental, monitoring is that for a particular individual, it takes into account exposure from all routes of absorption. For example, for workplace exposure to organic solvents, skin absorption may be a significant route of entry of the solvent into the body, and ambient environmental air monitoring might be less useful as an indicator of exposure than biological monitoring. Furthermore, environmental monitoring at the workplace would not account for non-occupational or extraoccupational exposures. A person exposed to organic solvents at work may have additional exposure at home as a result of hobbies or other non-occupational activity.

While the term ‘biological monitoring’ has previously been used to also include clinical procedures (e.g. periodic X-rays, blood tests, symptom enquiry, etc.) for monitoring the health status of exposed workers, it is preferable to make a clear distinction between the terms ‘biological monitoring’ (used for assessing exposure), and ‘biological effects monitoring’ and ‘health surveillance’ (used for detecting effects).

Biological monitoring standards

The Biological Exposure Index (BEI) represents the levels of determinants that are most likely to be observed in specimens collected from healthy workers who have been exposed to chemicals to the same extent as workers with inhalation exposure at the TLV (ACGIH 2017). Exceptions would be made for chemicals for which TLVs are based on non-systemic effects, for example, irritation; and for chemicals with significant routes of entry via additional routes of entry (usually percutaneous absorption).

The ACGIH cautions that BEIs are not able to clearly distinguish hazardous from non-hazardous exposures. Biological variation in individuals may sometimes result in measurements in individuals to exceed recommended BEI levels without an increased health risk. BEIs are also not intended for use as a measure of adverse effect or diagnosis of occupational disease. However, if measurements of the individual or group of workers persistently exceed the BEIs, the cause of the excessive values should be investigated, and measures should be taken to reduce the exposure.

Biological effects monitoring

Biological effects monitoring refers to the measurement and assessment of early biological effects, of which the relationship to health impairment has not yet been established, in exposed workers to evaluate exposure and/or other health risk compared to an appropriate reference. Health surveillance of workers is a common modality of biological effects monitoring. Examples are audiometry for noise-exposed workers, and clinical examination for skin lesions in workers exposed to polycyclic aromatic hydrocarbon compounds in tar, pitch, and bitumen. Biological markers are also used where relevant, including the detection of alterations in enzyme levels (e.g. cholinesterase for workers exposed to organophosphorus or carbamate pesticides), or other biochemical changes such as delta-aminolaevulinic acid in urine of workers exposed to inorganic lead, or beta-2 microglobulin in the urine of cadmium exposed workers. These changes do not necessarily lead to any direct overt pathological damage in an individual, but may reflect effects that are reversible on removal of the worker from further exposure.

Biomarkers can be used to monitor exposure, effect, or susceptibility. A single biological specimen may contain several biomarkers, each of which with the potential to be used as in occupational and environmental health. For example, there have been occupational stress studies that measure levels of salivary cortisol (a stress hormone) and secretory Immunoglobulin A (a marker of effect) (Koh and Koh 2007). However, not every biomarker correlates well with the level of exposure, effect, or susceptibility. There are also other challenges, such as the compatibility of collection methods, stability of biomarkers, and other factors confounding the measured levels of biomarkers, such as age, diurnal variations, medications, and health behaviours (e.g. smoking).

The availability of genetic tests to identify susceptible workers raises issues of ethics, individual privacy, right to work, and the relevance of such tests. Given the limitations of individual molecular biomarkers in assessing health risk, and the multifactorial nature of environmental disease, more work needs to be done to develop our understanding of the exposome, which is the constellation of all exposure events (exogenous and endogenous, including lifestyle) from conception to death. The integrated knowledge of the exposome and our genome may allow us to subsequently address all the factors that affect the health of our workforce and better control those that are work-related (Schulte and Hauser 2012).

Risk management

Prevention and control of occupational disease can take place at various levels, such as at the national level, at the level of the workplace itself, or measures directed at the individual worker.

Primary prevention aims at reducing the occurrence of disease by eliminating the causal factors contributing to disease or reducing workplace exposure to safe levels. Examples are banning the use of asbestos and reduction of noise at its source to levels that do not cause hearing loss. Primary prevention with regard to chemicals requires either: (1) elimination of toxic materials and their replacement by less hazardous substitutes or (2) use of safe systems of work, and controls such as complete enclosure or local exhaust ventilation at the source of aerosol generation.

Secondary prevention aims to detect overexposure, or early reversible effects of disease in order to take corrective action. For example, regular monitoring of blood lead levels among exposed workers could indicate a potential for lead poisoning, or regular audiograms among noise-exposed workers may show temporary threshold shift (TTS). Removal of workers with TTS from further noise exposure, and subsequent containment of the source of the noise can allow recovery of hearing. Successful secondary prevention depends on the ability to identify work-related illness early and effectively through screening workers at high risk for occupational disease.

Tertiary prevention aims to minimize the consequences in people who already have established disease. This activity is primarily a curative and rehabilitative function and depends on availability of appropriate treatment.

However, even for acute poisonings, there are very few specific effective antidotes available. Hence, the focus should be on primary or secondary prevention.

Hierarchy of controls

Within the workplace, a hierarchy of control measures is often invoked for reducing occupational hazards. This consists of considering the following steps listed according to order of priority:

Hazard elimination or substitution.
Engineering controls.
Redesign of the workstation or work process.
Administrative controls and worker education.
Use of PPE.

Hazard Elimination or substitution

Elimination removes the health risk completely, and has been used for carcinogens like asbestos and benzene, or substances that can cause serious health effects such as heavy metals. For example, it is possible to produce new soldering materials that contain little or no cadmium at all, and the HSE in the UK has produced legislation for this elimination (Mason et al. 1999). Even for materials where total removal is not possible, elimination strategy through change-of-form approaches have been adopted. These include coating nanoparticles, or altering the physical state or particle size through pelletizing, or prilling to encapsulate nanoparticles (Schulte et al. 2016). These modified strategies reduce the hazardous exposure and may make it safer for the worker.

Substitution of the hazard with a less toxic alternative is another option. In the case of processes which use solvents, such as degreasing operations, a less toxic solvent such as 1,1,1 trichloroethane can be used, instead of the comparatively more toxic trichloroethylene or tetrachloroethylene. Selection of a less hazardous process or equipment also represents a meaningful control strategy. For example, substitution of a continuous process with an intermittent process usually results in a decrease in exposure. Instead of replacing an entire work process to reduce hazards,

equipment substitution may achieve the desired reduction in exposure. An example is use of a degreaser with a hoist instead of dipping components into solvents by hand.

Engineering controls

Automation, enclosure, or segregation of a work process, and the use of dampeners or mufflers to reduce vibration or noise have been successful engineering control measures used. Improved ventilation is also an effective and widely used control measure. Control of hazards by ventilation can be through local exhaust ventilation or general ventilation. The approach for implementing ventilation controls is firstly to evaluate sources and degree of exposure; secondly, to develop an engineering design; thirdly, to install a system based on the design; and lastly, to evaluate the completed system to ensure that the air contaminant has been effectively controlled. In healthcare, engineering measures such as negative pressure ventilation serve as an important airborne precaution strategy to minimize the transmission and propagation of infectious diseases such as SARS (Esswein et al. 2004).

Isolation is defined as the interposing of a barrier between a hazard and workers who might be injured or made ill by the hazard. Isolation may refer to storage of materials, such as flammable liquids, enclosure or removal of equipment to another area (such as noisy generators), or isolation of processes or of the workers themselves (e.g. by enclosing a sawmill worker in a soundproof ventilated booth to protect them from noise and wood dust). The petroleum industry, for example, uses automated remote processing in plants based on centralized computer control of process equipment. Workers are thus largely isolated from hazards except in maintenance operations and during process upsets.

Suppressing the substance by ‘wetting’ of dusty operations is another example of effective engineering control. Alteration of work practices can help to reduce exposure to hazards. An example is vacuuming cotton lint off spinning machines rather than blowing it off with compressed air, which creates airborne dust particles.

Redesign of workstation or work process

Workstation redesign to reduce unnecessary and repetitive bending or poor postures can minimize ergonomic hazards. Among computer operators, use of adjustable equipment, positioning of the workstation to reduce glare, and provision of appropriate work rest periods can prevent the occurrence of visual and musculoskeletal complaints.

Administrative controls and worker education

Administrative controls may be a viable alternative or an additional measure to reduce worker exposure to occupational hazards. This could take the form of job enlargement or job rotation, restriction of hours of work at a hazardous operation, or temporary job reassignment.

With administrative controls, the level of exposure to the hazard is not diminished; instead, the duration of exposure is reduced. For example, mandatory rest periods and shorter work hours for outdoor workers during extremely hot weather (as in desert environments) have helped to reduce the likelihood of heat stress. Another example is the reduction of overall noise exposure through rotation of tasks. In recent years, the allostatic concept of well-being and health premised upon the balance between work demands and restorative needs is getting renewed attention. It has resulted in more research into the benefits of alternations between physical and mental tasks within the same job to enhance the well-being of workers (Jahncke et al. 2017).

Training of workers to recognize work hazards, to work safely, and to know what to do in the event of an emergency is another important aspect of prevention. There may be considerable variability in exposure even among a group of workers supposedly performing the same work tasks. This variation can be explained by differences in hazard awareness, attitude, and practice of safe working techniques in different workers.

Programmes for encouraging personal hygiene constitute another approach to reducing exposure. The provision and use of showers and a change to clean clothes at the end of the working day is a practical personal hygiene measure. A subtle but potentially important route of exposure is ingestion of toxic agents through eating or smoking, at the workplace. To prevent such exposure, separate facilities for consumption of food away from production lines should be provided.

Personal protective equipment

The use of personal protective devices to prevent occupational ill-health should generally be considered as a last resort after all other methods for minimizing exposure to workplace hazards have been tried. PPE can never be as efficient a means of protection as engineering or process controls. Nevertheless, the use of PPE is often widely practised, perhaps because it is seen as a relatively low-cost measure that puts much of the onus on the worker for compliance with use. PPE can be useful for short-term (as for emergency rescue work) or infrequent exposure to occupational hazards. Respirators, gloves, protective clothing, ear plugs, and muffs are all common forms of PPE in use throughout industry. They can play an important role, provided that carefully designed PPE programmes are in place and that the devices are frequently and regularly checked.

PPE should be properly selected to be effective against specific hazards, for example, the choice of an appropriate glove for use with a particular solvent. Workers have to be trained to use the equipment correctly and to ensure that it is working effectively, such as respirator fit testing in the use of respirators. Worker compliance in the use of these devices has to be high, or its protective effects may be less than desired. Compliance can be an issue, because of discomfort, especially for workers in hot and humid climates. PPE also have to be properly maintained and replaced when necessary.

Secondary prevention

Pre-employment examinations

An often stated aim of pre-employment examination is to detect any mismatch between the job applicant's health and the intended job. It seeks to determine whether an individual is fit to perform a specified job without risk to himself or others. A decision can then be made by management as to whether or not the person should be hired. Cost considerations, concerns about inability to carry out the full range of work tasks, and possible harm to third parties are often given as reasons for rejection of an applicant.

There is little empirical evidence to support the usefulness of pre-employment examinations (WHO 2009). In practice, the detection rate for relevant clinical abnormalities is low (2% in prospective HCW in the UK)

(Whitaker and Aw 1995), such that the cost-effectiveness of the process is questionable. The low preventive effectiveness of pre-employment examinations (i.e. the effort to prevent one adverse outcome) implies that the medical assessment should consist of no more questions and tests than are required relevant to the specified job (de Kort and van Dijk 1997). There is an element of selection bias since individuals who are in poor health with existing clinical abnormalities are unlikely to be seeking employment.

Pre-employment examinations probably constitute one of the most frequent procedures performed by occupational health departments especially in developing countries. In many developed countries, there are laws prohibiting discrimination on the basis of health status. Individuals are hired primarily on the basis of their credentials and ability before being put through a *pre-placement examination* (Aw and Koh 2013). Subsequent adjustments to the job tasks or work environment can then be made if indicated for health reasons.

Where they are performed, the pre-employment examination or the pre-placement assessment can be used to obtain baseline data on health status or fitness, to inform and educate new workers about potential hazards in their work and the preventive measures that can be taken to safeguard their health. Immunization against diseases that may possibly be contracted on the job, and for which effective vaccines are available (for example hepatitis B, measles, mumps, and rubella), should also be given. Some genetic disorders which can be identified at the pre-employment stage may enable suitable advice to be given in regard to special care in handling chemicals at work, for example, people with glucose-6-phosphate dehydrogenase deficiency are at risk of haemolytic anaemia on exposure to naphthalene and fava beans. People with serum total alpha-1-antitrypsin deficiency may be susceptible to smoke, fumes, and other respiratory irritants.

Statutory periodic medical examinations

The aim of statutory medical examinations is to prevent special groups of ‘at-risk’ workers from developing serious occupational diseases. These may include workers exposed to heavy metals, silica, asbestos, benzene, radiation, and noise. Regular health examinations, which are specific for the type of hazard the worker is exposed to, are conducted. Workers found to

have signs of overexposure to the hazard or with early signs of disease can be removed from further exposure. They can be given alternative work until they are fit to return to their former jobs. Furthermore, if signs of overexposure are detected, additional control measures can be taken to reduce the exposure at source and prevent other workers from being similarly affected.

Special groups of workers are required to undergo periodic medical examinations for protecting the health of the public, for example, public transport operators, pilots, and food handlers.

Notification of occupational diseases

Most countries require the statutory notification of occupational diseases to the regulatory bodies. This allows investigation, confirmation, and follow-up of cases by the authorities, and an analysis of trends over time. A single notified case may indicate poor control of work hazards that can pose a risk to other workers in the same work environment. The responsibility for notification has involved doctors, employers, or employee representatives, and varies between countries. Many countries produce a list of notifiable occupational diseases. This can be different from a list of prescribed diseases for which individuals may obtain financial compensation.

Notification serves as an additional means of control of occupational diseases. It should initiate a chain of events, starting from investigation and confirmation of the index case, and active case finding of other affected people. Recommendations for specific preventive measures at the workplace are then prescribed. The authorities would follow-up by ensuring that the recommendations have been implemented. If necessary, further evaluation of the effectiveness of the preventive measures can be made.

Tertiary prevention

Tertiary prevention involves mainly early treatment and rehabilitation. For occupational ill-health, affected workers should be removed from further exposure, and the appropriate medical treatment given as necessary. Examples of appropriate treatment include prompt first aid after an injury, chelation for severe cases of heavy metal poisoning, atropine and aldoximes for organophosphate poisoning, antidotes for cyanide poisoning, use of

calcium gluconate for hydrofluoric acid burns, and hyperbaric treatment for compressed air illness. Treatment would also include prompt provision of clinical supportive measures.

Planning for emergency response

Occupational health physicians play a central role in emergency preparedness and response. The American College of Occupational and Environmental Medicine identifies this domain as one of ten core competencies of the occupational health practitioner (ACOEM 2010). Occupational physicians are equipped with both clinical knowledge as well as an in-depth understanding of the work environment, processes, and workforce. They are therefore in a unique position to support, and sometimes lead, in emergency preparedness and business continuity planning and response.

Rehabilitation

Rehabilitation of workers is another important aspect of occupational health practice. Management, co-workers, occupational health professionals, and the injured worker have to work together to ensure that suitable alternative duties are provided, and that any work restrictions or physical limitations are understood. There should be clear short- and long-term goals in rehabilitation, and alternative duties should be meaningful and contribute to production.

Return to work

Return to work (RTW) is an important therapeutic goal for the injured worker. Studies have shown that when the medical management of the injured or ill worker includes attention to occupational issues with a view to early RTW, they tend to have faster recoveries and a more sustainable time on the job. In contrast, after more than 12 weeks off work, there is a 50% probability that the worker will still be away from work at the 1-year mark (ACOEM 2017a).

Planning for RTW should commence early in the course of treatment between the occupational physician and the primary physician (where applicable). Important considerations include the impact of the medical

condition on functioning and work ability, identification of obstacles to RTW (e.g. addressing misconceptions about illness and work), and early engagement of the employer in discussions on work adjustments and accommodations. Success in RTW often extends beyond managing physical functioning, to the complexities related to beliefs, roles, and perceptions of many stakeholders (e.g. patients, employers, co-workers) (MacEachen et al. 2006). Other important determinants to maximize positive outcomes in RTW programmes include securing employers' and organizational commitment, having dedicated and well-trained RTW coordinators, focusing the RTW plan on work participation rather than restrictions, and incorporating a plan which does not disadvantage co-workers (Skivington et al. 2016).

The assessment of work ability centres around three parameters, namely risk (chance of harm to the patient, co-workers, or the general public); capacity (refers to concepts such as strength, flexibility, and endurance); and tolerance (the ability to tolerate sustained work or activity at a given level) (Talmage et al. 2011). Of these, only capacity may be measurable to some degree of precision. Risk assessment is often dependent on logical deduction or expert consensus, whereas the ability to tolerate sustained work is a psychophysiologic concept which relies heavily on the motivation of, and incentivization available to the patient.

Workplace accommodations are also important to reduce barriers to RTW. Studies have shown that workplace interventions are important in reducing further sickness absence in injured workers who returned to work, and for improving pain and functional status among those with musculoskeletal disorders (van Vilsteren et al. 2015).

Workers' compensation

In many countries, workers who are injured at work or fall ill from hazardous work exposures are eligible for compensation. Workers' compensation is designed to provide income support, medical payments, and rehabilitation payments to workers injured on the job, as well as to provide benefits to the family and dependants of fatally injured workers. Most industrialized countries have workers' compensation programmes. In some countries, certain categories of workers, for example, domestic helpers are excluded. In many countries, employers have social insurance to give protection to employment injury victims. The principle of social

insurance is that of sharing of risks and pooling financial resources. A social insurance scheme establishes a public channel through a government department or government supervised body, which oversees procedures of screening, determination of award and payment of benefits.

Benefits are payable for temporary incapacity or permanent incapacity, and include survivors' benefits for those killed at work. Guidelines for assessment of disability are available in most countries. The final assessments for disability are made when the worker's medical condition has stabilized, and not likely to improve or deteriorate further.

Future challenges in occupational health

The practice of occupational health has evolved fairly rapidly over the last half a century. From the prevention and management of 'conventional' occupational diseases, occupational health burdens have shifted in tandem with global changes to employment patterns, demographic trends of the workforce, and the introduction of new technologies. This is more apparent in developed countries because of the relative decline in centuries-old occupational diseases with improvement in hazard reduction and control measures. The advent of information and communication technologies in the workplace, and its integration into the work ecosystem, fundamentally changes work patterns, duration, and intensity. With this, work-related stress and other mental disorders are replacing traditional occupational diseases as a leading cause of occupational morbidity in many parts of the world.

Advances in material science and engineering technology have enabled many occupational hazards to be eliminated, substituted with safer alternatives, or controlled through limited exposures to at-risk workers. However, the increase in life expectancies also means that workers are working longer years into elderly age, thereby bringing non-communicable diseases burden into the occupational fitness equation. It is likely that the demand for, and utilization of occupational health resources will rise over the years, given the ageing workforce and possibly the increasing complexity of cases (ACOEM 2017b). In the years ahead, the focus of management of occupational diseases and injuries must not only be restricted to clinical treatment alone. There is strong evidence to support

vocational rehabilitation, with the emphasis on early RTW as a therapeutic goal. This holistic and integrated occupational health model of care will likely define the standard of care in the future. In addition, occupational health has also evolved to consideration of health issues beyond the ‘factory gate’, as the discipline has much in common with environmental health and encompasses the philosophy and principles of good public health practice.

To address these contemporary and future challenges, a strategic change in occupational health practice will be one that will become more public health-centric (Harrison and Dawson 2016). From mainly addressing occupational hazard reduction and treating acute toxicities and injuries of workers, there will be a paradigm shift to the preventive care approach of the worker’s holistic health. This means that health interventions will not only be limited to occupational and work-related disorders, they will be extended to the primary prevention and management of chronic diseases under a Total Workplace Safety and Health framework. Occupational health practice of the present and future will therefore be centred not only on a safe workplace, but also on the concept of a healthy workplace. The promotion and maintenance of health and well-being may also be implemented at a broader community-level, with the knowledge that the worker is an integral part of a larger ecosystem and that health-seeking behaviours often achieve greater success when implemented under conditions where there is group participation and peer support.

Conclusion

The importance of occupational health lies in its emphasis on prevention, and in this respect it shares common objectives and strategies with public health. Occupational health focuses mainly on a specific group in the community— workers. Notwithstanding, there is convincing evidence that many of the public health issues of the future, such as medical needs associated with ageing populations and the increasing prevalence of non-communicable diseases, will also have a significant impact on the occupational health landscape. The socioeconomic imperatives of the Industrial Revolution had propelled the development of occupational medicine in the last two centuries. It is almost certain that changing needs of future economies and demographic shifts in the global workforce will

also have a great impact on shaping and defining the evolution of tomorrow's occupational health.

Toxicology and environmental risk analysis

David Koh and Ro-Ting Lin

Introduction to toxicology and risk analysis

Toxicology is the study of poisons. In theory, any substance can cause harm to health. To paraphrase the physician-alchemist Paracelsus, ‘It is only the dose that distinguishes a poison from a remedy’. To that we can add that the route of entry into the body can also determine the extent of injury or ill health. In practice, most poisons are either chemicals or biological materials that cause severe effects in relatively small doses. Poisonous substances that contaminate the environment can lead to an increased risk of ill health in exposed populations. The level of risk is a function of the extent of exposure and the susceptibility of those exposed. An understanding of toxicology is essential to determining and managing environmental risk.

Risk analysis has been defined as ‘a process consisting of three components: risk assessment, risk management, and risk communication’ (Food and Agriculture Organization and World Health Organization 2009). Environmental risk analysis is a broad field, encompassing risks to ecosystems and materials as well as to human health. This chapter discusses human health risks only. The goal is to synthesize toxicology and risk analysis as a basis for evaluating risks to human health posed by hazardous agents in the environment. Other disciplines, such as epidemiology and exposure assessment, are also required to better understand risk, and for many specific agents these disciplines will provide the primary information needed for risk assessment, risk management, and risk communication.

Toxicology has these two important roles in environmental risk analysis:

To ascertain cause and effect relationships linking hazardous agents to adverse effects in humans or the general environment.
To develop techniques capable of preventing these problems.

Toxicologists usually approach questions of disease causation by starting with the chemical or physical agent and studying its effects in laboratory animals or in test-tube systems. Modern toxicology also develops tools, primarily through molecular biology and advanced computational techniques, capable of probing the extent to which a given disease in an individual is caused by an external agent. This reverse approach, starting with disease and moving toward determining cause, is enabled by the increasing ability of epidemiology to link subtle biological markers indicative of early effects to biological markers indicative of exposure.

Toxicology is also an important discipline in the primary and secondary prevention of human health effects. When toxicologists understand the mechanisms by which chemical or physical agents cause biological effects, they can develop tests to help prevent further spread of harmful chemicals or promote early detection of potential adverse effects.

General concepts of toxicology relevant to risk analysis

Knowledge about poisons extends back to the beginning of history, as humans became aware of the toxicity of natural food components. Toxicologists credit Paracelsus with the first law of toxicology, that the dose makes the poison. Two other laws underlie modern toxicology: that chemicals have specific biological effects, a maxim credited to Ambrose Pare (Goldstein and Gallo 2001); and that humans are members of the animal kingdom.

The ‘laws’ of toxicology

The following section discusses the ‘laws’ and general concepts of toxicology pertinent to understanding how a chemical or physical agent acts in a biological system. The focus here is on the biological response to an agent, rather than on the intrinsic properties of the agent. These are the three ‘laws’ of toxicology:

The dose makes the poison.
Chemical/physical agents have specific effects.
Humans are animals.

The first law: the dose makes the poison

Exploration of the relation between dose and response is central to toxicology. There are two main types of dose–response curves (Fig. 7.4.1). One is an S-shaped curve characterized by having no observed effect at the lowest doses, gradual development of an increasing response as the dose increases followed by a linear phase of increase in relation to dose, and, eventually, a dose level at which no further increase in response is observed. Of particular pertinence to environmental toxicology is that this curve presumes that there exists a threshold level below which no harm whatsoever is to be expected. There is ample scientific basis for the existence of thresholds for specific effects. For example, one drop of undiluted sulphuric acid splashed on the skin is capable of producing a severe burn. Yet one drop of pure sulphuric acid in a bathtub of water is sufficiently dilute to be without effect. Thresholds for an adverse effect will differ among individuals based upon a variety of circumstances, some genetically determined and others representing stages of life or other specific circumstances. In the example of sulphuric acid on the skin, there are genetically determined differences in susceptibility related to the protective presence of skin and hair. Babies will be more susceptible than adults; and skin that is already damaged will be at particular risk. The S-shaped dose–response curve is assumed to fit all toxic effects except those that are produced by direct reaction with genetic material.

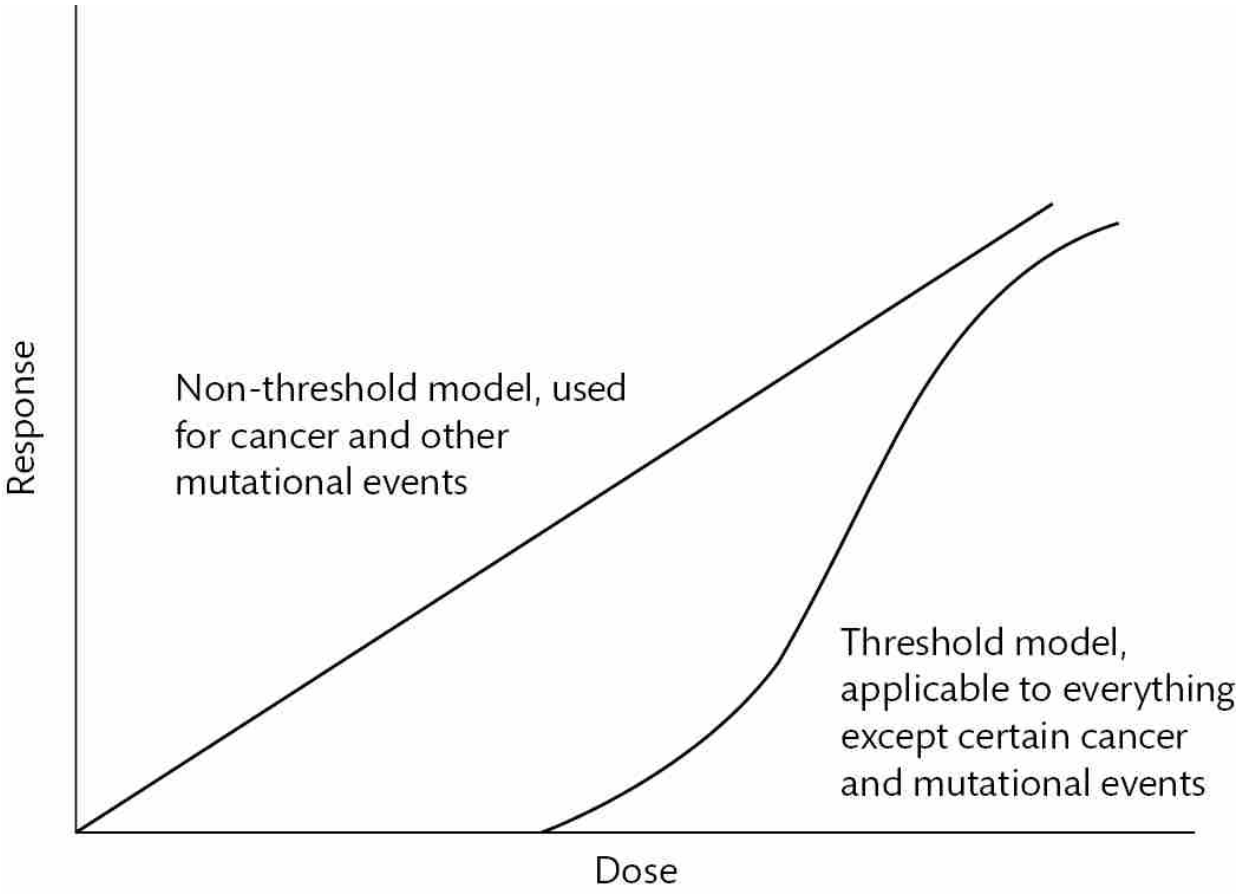

Fig. 7.4.1 Dose–response curve.

The second general type of dose–response curve covers endpoints caused by persistent changes in the genes. For example, in cancer, a somatic mutation occurring in a single cell results in a clone of cancer cell progeny. Another example is inherited mutations of the genetic components of cells involved in reproduction. It is believed that a single change in DNA can alter the genetic code in a way that can lead to a mutated cell. It follows that any single molecule of a carcinogenic chemical or packet of physical energy, such as ionizing radiation, that can alter DNA is theoretically capable of causing a persistent mutation. This presumption—that a single molecule or ionizing ray could change a normal cell to a cancerous cell—implies that there is no threshold below which the risk is zero. The resultant dose–response curve thus starts at a single molecule. As a further simplification, the shape of the curve can be linear in that the risk of two molecules of a DNA-altering chemical causing a mutation is conceivably twice that of one molecule, and so on, until a dose level results in dead cells.

Features of both S-shaped and linear dose–response curves occur in the human body's response to allergens. It is likely that a relatively large dose of an allergen is required to first sensitize an individual (i.e. the threshold dose for sensitization may vary with the agent and the individual). However, once sensitized, the affected individual may react to even molecules of the causative agent, with no apparent threshold for elicitation of a reaction.

There are also a few chemicals that have a U-shaped dose–response curve, where high levels of exposure cause harm and insufficient exposure leads to a deficiency which results in ill health. Examples are fat-soluble vitamins and essential trace minerals. Excess vitamin D intake causes hypervitaminosis D, and vitamin D deficiency leads to rickets and osteomalacia. There is, therefore, an ideal range for vitamin D levels which results neither in deficiency nor poisoning.

The second law: chemicals have specific effects

Understanding that chemical and physical agents have specific effects is in essence no different from recognizing that possession of a gun does not make one a murder suspect if the victim was stabbed to death. The law of specificity is well understood by the general public in terms of drugs: aspirin will help with your headache but is useless for constipation, while laxatives have the opposite effect. However, various surveys suggest that the selectivity of the effects of environmental chemicals is not widely understood and that many believe a chemical that can cause cancer in a particular organ can cause cancer and other diseases anywhere in the body. Some chemicals may cause malignancy in more than one body site (e.g. asbestos can cause lung cancer, peritoneal mesothelioma, and laryngeal cancer), but in general, chemical and physical agents are highly specific in their effects.

The specificity of effects is due to both chemistry and biology. Understanding the relationship between chemical structure and biological effect has been central to both pharmacology and toxicology. Structure activity relationship (SAR) is often used as a means to design a chemical with a specific effect that might be useful as a therapeutic agent. SAR is also used to predict whether a new chemical being readied for manufacture might be of potential harm. While SAR is a useful tool being further improved through modern computational approaches, its predictive value remains too

limited for use with a potentially toxic agent without recourse to additional testing. For example, only one simple methyl group separates toluene from benzene (only the latter known to cause bone marrow damage and leukaemia); ethanol from methanol (the latter causing metabolic acidosis, renal failure, and blindness); and *n*-hexane from either *n*-heptane or *n*-pentane (only *n*-hexane is responsible for peripheral nerve damage). These examples of specificity reflect both the formation of toxic metabolites, such as active species derived from the metabolism of benzene, and the interaction of a chemical or its metabolite within specific biological niches, such as the diketone metabolite (2,5-hexanedione) of *n*-hexane within neuronal axons.

Specificity of effects is also conferred by cellular processes that cause certain cells to be more susceptible to environmental agents. For example, red blood cells have the iron-containing protein haemoglobin that is responsible for the transport of oxygen. Toxicity through alteration of efficient oxygen delivery occurs through certain specific mechanisms. One is through the oxidation of the reduced ferrous form to the ferric form of iron, known as methaemoglobin, which can no longer carry oxygen. This occurs with a limited number of agents (e.g. nitrates and phenols) that, once within the red blood cell, are capable of oxidizing intracellular iron. Another specific mechanism of interference is exemplified by carbon monoxide. This otherwise relatively inert gas has a physical chemistry that sufficiently resembles oxygen so that it is able to tightly combine with the oxygen-combining site of haemoglobin, thereby displacing oxygen. There are many other examples in which a normal body process is disrupted by an exogenous chemical through a specific chemical alteration, such as oxidation or covalent addition, or by fitting into a niche designed through evolution to accommodate a necessary internal chemical which it superficially resembles.

The third law: humans are animals

The conceptual foundation for extrapolating from animals to humans is central to modern toxicology. The basic principles of cell function are common to all of biology: all cells must obtain energy, build structure, and release waste. Cell function in complex organisms, such as humans, is highly specialized, but there is still great similarity in cellular and organ function among mammals, which facilitates extrapolation from one species to

another. In general, a kidney poison in one species is likely to be a kidney poison in another, although there are certainly exceptions. As an example, arsenic is a human carcinogen with a lack of evidence for carcinogenicity among other animals.

However, despite similarities in effects, dose–response considerations often vary substantially between species, reflecting differences in absorption, distribution, metabolism, excretion, function, and target organ susceptibility. Understanding the factors responsible for interspecies differences greatly facilitates extrapolation from animals to humans. Once elucidated, the role of different absorption rates, metabolism, or other factors can be taken into account, often through a mathematical approximation that has come to be called physiologically based pharmacokinetics (or toxicokinetics).

The use of alternative methods to replace animal testing is becoming popular. For example, under the 2006 Registration, Evaluation, Authorisation, and Restriction of Chemicals (REACH) regulation in the European Union (EU), companies that manufacture or import chemical substances in quantities beyond a certain volume are required to submit reports of testing on vertebrate animals. To avoid unnecessary animal tests, the European Chemicals Agency (ECHA) introduced the concept of alternative methods such as read-across, SAR, weight of evidence, and *in vitro* methods (European Chemicals Agency 2017).

Pathways of exogenous agents within the body

Absorption, distribution, metabolism, and excretion of exogenous agents can vary greatly across individuals and within the same individual depending upon, for example, stage of life and state of health. These variations are among the major reasons for individual differences in susceptibility to risks from exposure to toxic agents. Increased understanding of how the human genotype and phenotype affect absorption, distribution, metabolism, and excretion of exogenous agents, including foods, is providing insight into the oldest human question about disease: ‘Why is this happening to me?’ (Omenn 2000).

Absorption

Absorption of a chemical into the body occurs through ingestion, inhalation, and skin absorption. Depending upon the specific chemical, the route of exposure can have major implications for the extent of absorption and the resultant toxicity. For example, almost 100% of inhaled lead-containing fine particles are absorbed into the body, while a much smaller percentage of ingested lead is absorbed. Internal factors also affect absorption, particularly in the gastrointestinal tract. In the case of lead absorption, both iron and calcium deficiencies increase the absorption of ingested lead. The matrix of the exposure agent also may have an effect. For example, the rate at which benzene in gasoline is absorbed through the skin is likely increased by oxygenated components of the gasoline mixture, and the absorption of dioxins from contaminated soil can vary enormously (Umbreit et al. 1986). The American Conference of Governmental Industrial Hygienists provides a 'skin' notation for chemicals that can be absorbed through the skin to cause systemic effects following exposure (American Conference of Governmental Industrial Hygienists 2013).

Often, a single route of absorption is dominant. But in many instances, more than one route may be important. For example, exposure to chlorinated disinfection products in drinking water systems, or to gasoline contamination of well water through a leaky underground storage tank, is usually thought of solely in terms of the ingestion of water. However, during showering, there is likely to be both inhalation and transdermal absorption, and if groundwater is contaminated, there can be off-gassing from the soil into the home. Epidemiological studies of the potential adverse consequences of water contamination need to take all of these exposure routes into account (Arbuckle et al. 2002).

Less common routes of absorption are intravenous, intramuscular, intraperitoneal, and sublingual, or via suppositories. These occur mainly in animal experiments or in human drug delivery. A novel route of absorption is the translocation of nanoparticles deposited in the nasal area via the olfactory nerves directly into the brain (Oberdorster et al. 2004). For example, inhaled airborne magnetite particulate matter (PM) has been found to cross the damaged olfactory unit, pass through the axons of the olfactory nerve, and enter the brain, which can potentially be related to neurodegenerative diseases such as Alzheimer's (Maher et al. 2016).

Distribution

Once inside the body, chemicals are transported by the blood. Distribution is determined by factors including the route of absorption, the chemical and physical properties of the substance, and the barriers that compartmentalize the body.

The route of absorption affects the different pathways through which chemical substances are distributed. Most compounds absorbed in the gastrointestinal tract go directly to the liver and may go no further. The liver has great capacity to detoxify many absorbed chemicals, especially when the chemical is absorbed by the digestive system and enters the hepatic portal system into the liver before it reaches the rest of the body. Enzymes in the gastrointestinal bacteria, lumen, gut wall, and liver contribute to this first-pass effect, which may greatly reduce the level at which a particular agent remains bioavailable in systemic circulation. On the other hand, inhaled agents go first to the lungs or other parts of the respiratory tract and then to general circulation, without being filtered through this ‘first-pass’ effect.

The specific chemical and physical properties of a substance and their affinity for certain organs or tissues also affect distribution of a chemical substance. Small inhaled particles tend to be distributed deep within the respiratory tract, while larger particles are filtered out in the nose or are trapped and cleared by the bronchiolar mucociliary escalator. Chemicals that are poorly soluble in water, such as oils, usually distribute within fatty tissues. Organ-specific factors are also important. For example, a specific pump located in the thyroid gland facilitates uptake of iodine and makes the thyroid particularly vulnerable to the adverse impact of radioactive iodine.

Some tissues, such as the blood-brain barrier and the placental barrier, limit the distribution of chemical substances. The blood-brain barrier, with its capillary endothelial cells, can protect the central nervous system. Only fat-soluble substances, such as alcohols, can cross the blood-brain barrier. The placental barrier prevents many toxicants from reaching the foetus but allows oxygen and nutrients to pass from mother to foetus (Burton et al. 2016).

Metabolism

Metabolism, in the narrowest sense of the term, refers to alteration of chemicals by the body. The major metabolic function of the body is to alter food into energy or structural materials. Metabolism of xenobiotics is often

protective, converting unwanted absorbed materials into chemical forms that are readily excretable. Thus, a fat-soluble agent can often be converted into water-soluble agents capable of being excreted in the urine. However, for certain classes of chemicals, metabolism results in conversion of relatively inactive compounds into harmful agents. For example, some carcinogens, including polycyclic aromatic hydrocarbon components of soot and benzene, require metabolic activation to change from pro-carcinogens to ultimate carcinogens.

All organs appear to have metabolic capability, often related both to organ function and to susceptibility to toxic agents. Understanding the specific enzymes and enzyme families responsible for metabolism within cell types is important to understanding why chemicals have specific effects in specific organs.

In the case of inhaled benzene, about 50% of the body burden is exhaled unchanged as the parent compound, and the rest is metabolized to potentially toxic metabolites. Slowing down benzene metabolism leads to an increase in the relative amount that is exhaled rather than metabolized, and thus a decrease in bone marrow toxicity. Individuals with what appear to be genetically determined increases in benzene metabolism to toxic metabolites, or decreases in the detoxification of these metabolites experience increased haematological risk. The effects of having both polymorphisms together appear to be at least additive and perhaps multiplicative in increasing the risk (Rothman et al. 1997; Kim et al. 2007). The application of genomics and proteomics to metabolism is often known as metabolomics.

Excretion

Excretion of chemicals from the body occurs through a variety of routes, including the gastrointestinal tract for unabsorbed compounds and for compounds dissolved in bile, and the renal tract (e.g. in urine) for water-soluble agents of appropriate molecular weight and charge. Significant excretion of volatile compounds can occur through the respiratory tract. Other routes of excretion include sweating and lactation, the latter which may put the breastfed infant at risk.

Multiple chemical interactions

Toxicological studies of absorption, distribution, metabolism, and excretion are often performed for single chemicals. Yet in real life, multiple and combined exposures are the norm rather than the exception. For such situations, the possibility of additive or synergistic effects, or potentiation or antagonism of effects, has to be considered. For example, exposure to two organophosphate insecticides may result in a simple additive adverse effect. In the case of exposure to carbon tetrachloride and ethanol, or asbestos exposure and cigarette smoking, the combined effects are synergistic. Antagonistic interactions take various forms. Functional antagonism is exemplified by the opposing functional effects of combined exposure to barbiturate and norepinephrine. An example of chemical antagonism is adding BAL (British anti-Lewisite) to inactivate metal ions through chelation. Dispositional antagonism is made use of when treating poisoning with charcoal, or when using an emetic or a diuretic. Receptor antagonism is seen in the case of naloxone as treatment for morphine overdose.

Risk assessment

Risk assessment follows two separate streams of toxicological reasoning: (1) for toxic agents implicitly or explicitly assumed to have a threshold, and (2) for carcinogens. Chemical safety assessment developed from simplified approaches such as studies on laboratory animals to determine the dose (LD_{50}, expressed usually as mg/kg body weight) or the concentration (LC_{50}, expressed as parts per million of the substance in air or water or other medium) capable of killing 50% of the test animals. The observed LD_{50} or LC_{50} was used as a basis for extrapolating to permissible levels in humans, often using several tenfold safety factors. Such protective factors were based on the concern that humans as a species could be more sensitive than the laboratory animals; that there would be greater variability in sensitivity among humans than among genetically inbred laboratory animals all raised in a similar environment; and that there could be adverse non-lethal effects that should be avoided. A presumptive tenfold safety factor has been added specifically to protect children, in recognition of their greater risk to certain chemicals compared to adults (National Research Council 1993).

The inherent assumption in the safety factor approach is that there is a threshold dose level below which there are no adverse effects. However, in

carcinogenesis, a single mutation could be the basis for the entire cancer process. As each molecule of a carcinogen, at least theoretically, could cause this mutation, a threshold cannot be assumed, and thus, in a simplified expression, there is no level of exposure that is without risk. However, almost all DNA damage is repaired by efficient cellular processes. Some unrepaired mutations are lethal to the cell, and as dead cells do not reproduce, these mutations cannot be the basis for cancer or inherited abnormalities. The majority of mutations are silent and have no discernible effects. Accordingly, the risk of any one molecule actually causing cancer is infinitesimally small—literally trillions of molecules of carcinogens are inhaled with every cigarette, yet not all cigarette smokers develop cancer. However, the assumption that there is no zero risk in regards to chemical and physical carcinogens has a major impact on communicating to the public about cancer risk.

There are known circumstances in which cancer causation does depend upon exceeding a threshold level of a chemical (e.g. the mechanism by which saccharin causes bladder cancer in laboratory animals appears to proceed through the precipitation of saccharin in the bladder, which requires a dose sufficient to exceed the physicochemical processes determining saccharin solubility). However, prudent management of cancer risk usually assumes that a carcinogen is ‘guilty until proven innocent’ of having no risk-free level. In essence, the burden of proof is on industry to demonstrate scientifically that a cancer-causing chemical does indeed have a threshold.

The four major components of risk assessment are listed in Box 7.4.1.

Box 7.4.1 Components of risk assessment

Hazard identification: Determining whether a specific chemical or physical agent is causally linked to a specific endpoint of concern; that is, chemicals have specific effects, or the second law of toxicology.

Dose–response evaluation: Determining the relation between the magnitude of exposure and the probability of occurrence of the specific endpoint of concern; that is, the dose makes the poison, or the first law of toxicology.

Exposure evaluation: Determining who and how many people will be exposed; the routes of exposure; and the magnitude, duration, and timing of exposure.

Risk characterization: Describing the nature and often the magnitude of the human risk, including attendant uncertainty.

Hazard identification

Hazard is the potential for harm. It is an intrinsic property of a substance or situation. Risk is the likelihood of harm occurring (and the likely severity of the resulting effect). It is a function of both hazard and exposure: for example, asbestos fibres sealed in a ceiling of an office have the potential to cause health effects (hazard), but the likelihood of that occurring is low if the ceiling is left intact (risk). However, if the ceiling is demolished and dust containing the asbestos fibres is released, the risk to health can be considerable. The risk has changed because of the circumstances of exposure. Identifying the presence of a hazard is just one step in risk assessment; subsequent steps, such as exposure evaluation, are key to determining what preventive action needs to be taken to reduce the risk.

Regulatory and quasi-scientific bodies often use a weight-of-evidence approach to identify a hazard. In essence, a panel of scientists judges whether sufficient evidence exists to identify an agent or condition as posing a risk of a specific effect in humans, or in some other target such as an ecosystem. In the United States, the approach to permitting the marketing of a new chemical is to have an internal Environmental Protection Agency scientific group review the chemical structure and other data submitted by industry. Similarly, the US Food and Drug Administration relies heavily on an advisory committee process to review evidence of efficacy and toxicity before approving a new pharmaceutical agent or medical device.

Formal weight-of-evidence approaches have been particularly useful in evaluating potential human carcinogens. The International Agency for Research on Cancer (IARC) of the World Health Organization uses this approach, convening expert panels to evaluate the evidence for carcinogenicity of specific chemical compounds or defined mixtures (e.g. diesel fuel, wood dust). The focus is on the weight of the evidence for carcinogenicity based upon carefully framed criteria—considering animal toxicology, epidemiology, mechanistic information, and exposure data—but not on the potency of the compound as a cancer-causing agent. When assigning a score for carcinogenicity, IARC now includes increased weight on understanding toxicological mechanisms (Cogliano 2004). Many countries use the information produced by IARC to determine governmental regulatory approaches. In the United States, the IARC listing of carcinogens has no official status, but it carries much weight with regulators, as does a

similar process used by the National Toxicology Program for its Report on Carcinogens (National Toxicology Program 2015).

Relatively few chemicals have been reported capable of causing cancer in humans. Of the perhaps 70,000 to 100,000 chemicals in commerce, about 100 are known to be human carcinogens. To an extent, this represents the success of environmental health science in providing tools that guide chemical manufacturers away from new chemicals that are potentially carcinogenic. During the chemical development process, early application of simple test batteries that evaluate the potential for mutagenesis or other predictors of cancer causation provides a responsible chemical industry with the means to avoid producing carcinogens or other potentially harmful products—and the means to avoid the regulatory and toxic tort consequences of harming the public. The value of this primary preventive approach depends upon the availability of effective toxicological test batteries. Such tests depend upon a basic understanding of the chemical and biological processes underlying toxic effects. Unfortunately, the investment in using standardized test batteries for high-production-volume chemicals, and the major increase in such investments due to new requirements such as the EU REACH legislation (see section 5.5), has not been accompanied by recognition of the need to develop better and more effective tests to protect the public. Advances in molecular toxicology provide many opportunities to improve these test batteries (National Research Council 2007).

Dose–response evaluation

The key issues in dose–response evaluation involve how to extrapolate from the high doses at which an effect is observed in an animal or epidemiological study to the usually much lower levels of risk which are of public or policy concern. Crucial to extrapolation are assumptions about the shape of the dose–response curve). It must be emphasized that the levels of risk desired by society (e.g. in the range of less than 1 in 10,000 to less than 1 in a million over a lifetime) are usually too low to be scientifically verifiable. This is particularly true given that the endpoints of concern cannot be attributed solely to the environmental hazard under consideration, as illustrated in Box 7.4.2.

Box 7.4.2 Benzene and leukaemia in the United States

Based upon extrapolation from both epidemiological and animal studies, an individual's lifetime exposure to 1 microgram/m^3 benzene in air is estimated to result in an increase in the lifetime risk of leukaemia of 2.2–7.8 in a million (US Environmental Protection Agency 2002). In the United States, a reasonable average outdoor level of benzene is approximately 3 micrograms/m^3, which would predict a lifetime risk of 6.6–23.4 in a million caused by this benzene exposure. Regulatory approaches that decrease that outdoor background level by two-thirds to 1.0 micrograms/m^3 benzene nationwide would be estimated to decrease the risk of benzene-induced leukaemia by two-thirds. This would mean that nationwide, there would be 4.4–15.6 fewer cases of leukaemia per lifetime for every 1 million Americans, or a lifetime risk of approximately 10 in a million.

Assuming a 70-year lifetime, and 350 million Americans, one can estimate that there would be 50 fewer cases of leukaemia a year nationwide as a result of a two-thirds decrease in outdoor benzene levels. This is a very small percentage of National Cancer Institute's estimate of 62,130 new cases of leukaemia in the United States in 2017 (http://www.cancer.gov/cancertopics/types/leukemia). While preventing 50 leukaemia cases is socially desirable, there are no current epidemiological or animal toxicology methods that could scientifically validate these assumptions. A further complication is that for most of the US population, unregulated and highly variable indoor exposure to benzene, as well as to many other volatile organic compounds, far exceeds outdoor exposure. In fact, the major reason for a decrease in personal benzene exposure in the United States has been the decline in cigarette smoking, for smokers, and its restriction from public places, for non-smokers (Goldstein et al. 2011).

Exposure evaluation

Exposure evaluation determines the extent to which an individual is exposed to a toxic agent (i.e. determining the dose), and thus involves both monitoring of environmental and individual samples as well as modelling. This process is complicated because the selected indicators of exposure should be representative—reflecting the actual dose. Box 7.4.3 (A) demonstrates the complications of representative exposure. Note also that knowing the dose alone does not allow one to assess the risk posed by the toxic agent. The dose–response relationship may change under different exposure scenarios. Several factors related to exposure, such as timing (i.e. dose-time-response relationship), may mediate the dose–response relationship and should be considered during risk assessment, as illustrated in Box 7.4.3 (B).

Box 7.4.3 Asbestos and asbestos-related diseases

(A) Measuring asbestos exposure level and assessing mesothelioma risk

Asbestos has been classified as a Group 1 human carcinogen by the IARC. Exposure to asbestos can lead to cancer, such as lung cancer and mesothelioma. To estimate the risk of respiratory tract cancers in relation to asbestos exposure in occupational settings, airborne asbestos concentration measured by fibre per cubic centimetre (f/cc) or fibre per cubic metre (f/m^3) has been widely used as an indicator. However, asbestos also exists as a health threat in the general living environment, such as in older buildings and structures. Data on residential exposure are often lacking, which limits the estimation of cumulative exposure level, let alone lifetime mesothelioma risk. Researchers have applied an alternative method to calculate individual asbestos exposure level by analysing the asbestos in a lung sample. Based on a population-based study in the United Kingdom, the lifetime risk of mesothelioma is 0.02% per 1,000 amphibole fibres per gram of dry lung tissue (Gilham et al. 2016).

(B) Dose-time-response relationship between asbestos and asbestos-related diseases

A majority of mesothelioma cases are caused by occupational exposure to asbestos. The dose–response relationship between asbestos and mesothelioma may change with different age at first exposure. Epidemiological studies suggest that the lifetime mesothelioma risk increases with cumulative level of exposure, duration of exposure, and also the timing of first exposure. That is, early exposure to asbestos is likely to exacerbate the risk of mesothelioma and thus warrants long-term surveillance programmes that begin in childhood (Lacourt et al. 2012; Lacourt et al. 2017).

Exposure evaluation is central to managing environmental risks. Advances in the field of exposure science are particularly crucial to understanding aggregate and cumulative risk (International Life Science Institute 2003; US Environmental Protection Agency 2003). Aggregate risk takes into account the different pathways of exposure for the same chemical. Cumulative risk describes the multiple effects of different agents through different routes. In essence, this is an assessment of the impact of the mix of external synthetic and natural chemicals in which we all live. Cumulative risk assessment is particularly pertinent to environmental justice considerations.

The importance of exposure assessment to understanding risk is exemplified by investigations into potential adverse health consequences resulting from man-made and natural disasters. Notable examples include the attack on the World Trade Center in New York City in September 2001, and the earthquake and tsunami that destroyed the Fukushima Daiichi Nuclear Power Plant in March 2011. Careful evaluation of disease endpoints in relation to exposure will help unravel the highly litigious issue of whether responders or the general public have an increased incidence of disease from exposures related to an event or the clean-up process. New protocols and

tools to assess exposures resulting from man-made and natural disasters may help better evaluate the exposure–effect relationship (Lioy et al. 2006).

Risk characterization

The seemingly straightforward process of characterizing risk through hazard identification, dose–response evaluation, and exposure evaluation presents many challenges. To start with, those doing the characterization can put their own spin on the findings. For example, people are likely to respond differently to something characterized as 99% free of risk than to the numerically equivalent 1% likelihood of a serious consequence including death. Characterizing exactly who is at risk (the denominator) is also a challenge. Reporting risk in terms of the entire exposed general public can trivialize the risk experienced by a highly sensitive subpopulation, such as those with asthma.

Risk can be displaced from one country to another. For instance, in 2006, hazardous waste illegally sent from Europe and dumped in the Ivory Coast was reported to have caused 9,000 acute illnesses and 6 deaths in Abidjan (Greenpeace 2006, 2012). The Ivory Coast, lacking internal expertise, had to use its funds to hire a European company to retrieve, ship, and process the toxic waste. The European company that dumped the waste made a series of payments to the Ivorian government and to individual claimants without admitting liability. In July 2010, a Dutch court found the company guilty of illegally exporting toxic waste from Amsterdam and concealing the nature of the cargo, and imposed a fine on the company.

A long-standing debate exists on the extent to which numerical uncertainty, rather than a simple qualitative statement of the major sources of uncertainty, should be a routine part of risk characterization. Those in favour of routinely providing numerical boundaries that quantify the extent of uncertainty point out that the many estimates and default assumptions in a risk assessment provide wide ranges of uncertainty that should be presented to the risk manager and the general public.

Those in favour of more restricted use of quantitative uncertainty analysis point out that most risk assessments are scoping activities aimed at considering alternatives or developing priorities. Further, major societal decisions are often made on numerical estimates for which no uncertainty factors are given (e.g. gross domestic product, unemployment estimates).

Note that the qualitative issues underlying uncertainty in a risk analysis should always be transparent to the risk manager and affected stakeholders.

The future of risk assessment

Risk assessment as a formal process for evaluating environmental agents continues to evolve, and in the last few decades, more sophisticated approaches to assessing cancer risk and cumulative and aggregate risk have been developed. The use of molecular toxicology to replace standard default assumptions is particularly promising (National Research Council 2007). Just as in other natural sciences, advances in data handling and informatics provide opportunities to assess larger and more complex databases. Advances in epidemiologic methodology using biological indicators of exposure and effect based upon ecogenetics and other molecular biological techniques may be particularly fruitful (Omenn 2000). Conceptually, our genetic makeup loads the gun, but the environment pulls the trigger. Identification of subpopulations sensitive to environmental agents will challenge regulatory and legal interpretations of the many environmental health laws aimed at protecting susceptible populations.

Global harmonization of risk assessment has been underway for decades. This will particularly be needed to avoid the use of environmental health principles as a façade for trade barriers. Evidence-based approaches to toxicology, similar to those increasingly used in medicine, are a welcome development. It remains a challenge to use such approaches for risk assessments that depend heavily on extrapolation to levels of risk below the readily observable—that is, where evidence will be indirect.

The regulatory approach to protecting worker health from toxic chemicals is often based upon both a measurable workplace standard and a subtle measure of effect. Thus for benzene, there is a 1 part per million, 8-hour time-weighted average workplace air standard, as well as a requirement for routine blood counts. The latter informs the former, in terms of both whether unmeasured exposures may be occurring and whether a reconsideration of the allowable external standard is needed. Red cell, white cell, and platelet counts can be affected by a variety of common conditions (e.g. infections, iron-deficiency anaemia), thus surveillance findings must be carefully evaluated before any observations are ascribed to benzene exposure.

In contrast, environmental standards are almost always measures of external emissions or ambient levels of pollutants. Such standards are surrogates for the desired goal of avoiding adverse consequences to human health and the environment. Achieving a level of scientific knowledge that would permit direct evaluation of subtle biological precursors of adverse effects is a desired route to developing emission standards that are truly protective. There is much work in progress in this field of environmental health indicators.

The history of protecting human life from the consequences of environmental agents is the history of catching up to the adverse effects of otherwise beneficial new technology—starting with the human use of fire. A new technology with potential for both beneficial and adverse consequences is nanotechnology. Decreased particle size can result in unexpected new physicochemical properties, in part due to a very high surface-to-volume ratio (Helland et al. 2007). There is concern about what nanoparticles may do at the cellular level and whether current toxicological testing schemes and regulatory processes are adequate to protect against potential harm.

Multiwalled carbon nanotubes (MWCNTs) are a type of manufactured nanomaterial. As use of MWCNTs widens, increased exposure via raw materials and consumer products is expected. The MWCNT-7 version was classified as possibly carcinogenic to humans (Group 2B) by the IARC in 2014, following results from numerous *in vivo* studies (Grosse et al. 2014). In 2017, the IARC declared other MWCNTs, as well as single-walled carbon nanotubes, not classifiable for carcinogenicity to humans (Group 3) (International Agency for Research on Cancer 2017). However, toxicological principles are still relevant and central to the risk assessment process, as demonstrated in Box 7.4.4.

Box 7.4.4 Potential environmental risks of carbon nanomaterials

Scientists have identified concerns about the spread of nanomaterials in consumer products to the environment. Carbon nanomaterials (CNMs), for example, have been widely used in commercial products, such as rechargeable batteries, automotive parts, sporting goods, boat hulls, and water filters (De Volder et al. 2013). CNMs can be released into the environment via manufacturing facilities, landfills, wastewater treatment plants, or accidental release, further disrupting ecosystems (Nowack and Bucheli 2007). Several types of CNMs, such as C60 fullerene, multiwalled carbon nanotubes, and single-walled carbon nanotubes, could be adsorbed by and accumulate in plant roots where the soil or culture medium contains such CNMs.

CNMs have both positive and negative effects on plant growth. For example, CNMs may inhibit rice growth, as measured by shoot height and root length (Hao et al. 2018). However, CNMs have also been used as fertilizer, and carbon nanotubes are used in agricultural sciences to enhance plant growth, by positioning micro-tubes inside the plant to enhance the efficiency of water uptake (Vithanage et al. 2017). Although Bjorkland et al. found low bioaccumulation of carbon nanotubes in plants, invertebrates, and non-mammalian vertebrates (Bjorkland et al. 2017), the overall health risk of CNMs to humans via plant consumption, as well as the risk from environmental exposures, needs further assessment (Guinee et al. 2017).

Future developments in risk assessment are likely to include discovery of new risks from old agents in new forms of use, and estimation of the combined effects of low-dose exposure to mixed agents (Miller et al. 2017). With more scientific evidence showing health risks attributable to toxic agents will come more opportunities for scientists to provide timely and robust policy recommendations. To protect public and environmental health, we will need policies that promptly regulate the use and distribution of identified toxic agents. The challenge is to narrow the gaps between scientific evidence and policy application (Gross and Birnbaum 2017).

Regulatory system design drives the ways that the risk of chemicals can be controlled. Chemical agents are used in a wide range of industries to produce consumer products, and new technology may involve new use of such agents. However, the environmental risks of most chemicals have not been quantified: industrial production processes often grow and change too fast for adequate risk assessment to be conducted. In the mid-twentieth century, there was often insufficient toxicological information to estimate the environmental health risks posed by extensive consumption of all the new chemical substances. Some regulatory schemes, such as the Toxic Substances Control Act in the United States, enacted in 1976, were developed under the assumption that ‘a substance is safe, unless it can be proven unsafe’. This placed the burden of proof on the governmental agency conducting the risk assessment. Since the EU’s REACH passed in 2006, the regulatory paradigm has been shifting to a new assumption, that ‘a substance is unsafe, unless it can be proven safe’ (Krimsky 2017).

In addition, many of the established dose–response relationships address single toxic agents, as do the regulations that set exposure limits and standards. The cumulative impact of low-dose exposure to multiple toxic agents is often neglected. For example, according to the Environmental Impact Assessment Act in Taiwan, governmental approval of new industrial developments that exceed a certain production capacity requires a health risk

assessment. Yet the risk assessments performed have addressed only the incremental additional health risk associated with the new development, ignoring the cumulative health risk associated with industrial and other factors across the entire geographic area (Lin et al. 2016). If low-dose and long-term exposures to multiple toxic agents continue, people who are initially considered as a low-risk group can eventually become a high-risk group.

Although it is important to identify people at high risk in order to develop early prevention strategies (high-risk strategy), interventions for widespread environmental hazards should also cater to those at lower risk (population strategy) (Lanphear 2017); unless there is a compelling reason to exclude them. This is the concept of prevention paradox (see Box 7.4.5.)

Box 7.4.5 The prevention paradox

The prevention paradox, espoused by Geoffrey Rose in 1981, suggests that a large number of people exposed to low risk may generate more cases than a small number exposed to high risk. This is because when there is a small elevation in risk, the total burden of disease will increase more in the large group than in the small group. Conversely, an intervention that offers large benefits to the overall population might offer little benefit to the individual (Rose 1981). Two types of prevention strategy are the high-risk strategy and the population strategy. The high-risk strategy focuses on identifying high-risk individuals and providing individual protection. The population strategy focuses on controlling determinants of incidence and shifting the mean of hazard exposure to a lower level (Rose 2001).

An estimate of population health gains resulting from 22 new preventive interventions in the Netherlands from 1970 to 2010 suggested that three-quarters of the gains were attributed to the population strategy and one-quarter to the high-risk strategy (Mackenbach et al. 2013). It should be noted that these two strategies are not always in competition. Choices can be made between the two strategies when establishing risk prevention policies, but the primary concern should be controlling the causes of incidence (Rose 2001).

Risk assessments should not be one-off activities, but instead involve continued monitoring for potential or encountered adverse health effects through, for example, the development of new risk assessment tools or post-marketing surveillance. This is illustrated in the case study in Box 7.4.6.

Box 7.4.6 Case study: safety of genetically modified crops

Advances in genetically modified (GM) technology in foods, or genetically modified organisms 2.0, have brought on a rapid revolution of crops to meet the global demand for food both quantitatively and qualitatively. In the United States, common GM crops include canola, corn, cotton, soy, and sugar beet. Two types of health risks have arisen: direct risk from the intake of GM foods, and indirect exposure to herbicides used on GM crops.

Currently, the health risk from dietary intake of GM foods is believed to be low. Two National Academy of Sciences reviews, in 2000 and 2004, concluded that genetically modified organisms pose no unique hazards to health. However, the reviews also recommended the development of new risk assessment tools and post-marketing surveillance.

In contrast, the herbicides used on GM crops carry substantial health risks such as carcinogenicity. There has been a sharp increase of herbicides applied to GM crops in the past few decades. For example, the herbicide most widely used on GM crops is glyphosate, and its use in the United States increased by more than 250 times in the past 40 years (from 0.4 million kg used in 1974 to 113 million kg in 2014). The global use of this herbicide has increased by more than 10 times.

As glyphosate-resistant weeds became more widespread, *Enlist Duo*—a combined herbicide product containing glyphosate and 2,4-dichlorophenoxyacetic acid (2,4-D)—was introduced by a chemical manufacturing company. The United States Environmental Protection Agency (US EPA) first approved the use of *Enlist Duo* in 2014, and its use is projected to increase. The following year, in 2015, IARC classified glyphosate as a probable human carcinogen (Group 2A) and 2,4-D as a possible human carcinogen (Group 2B). In 2015, the US EPA revoked its approval of Enlist Duo, stating that the herbicide might be more toxic than previously thought. However, in 2017, the US EPA approved *Enlist Duo* once again, despite the lack of any significant change in its environmental and health assessments. These ever-changing developments raise new concerns about the safety of GM crops (Guyton et al. 2015; Landrigan and Benbrook 2015).

An important goal of evaluating human health risks is to reduce the population's exposure to toxic agents and improve environmental quality. While conventional risk assessments focus on the mechanism of toxic agents on human health, cumulative risk assessments should include both environmental sources of toxic agents and social determinants of exposure. An abundance of scientific literature shows that environmental health risks cause more burden in socioeconomically disadvantaged populations and communities—the same communities which have long been excluded from the decision-making processes resulting in environmental laws, regulations, and policies (Mohai et al. 2009; Kalnins and Dowell 2015).

Incorporating social determinants of health into risk assessment can promote environmental justice. While uneven exposure to environmental hazards is now well recognized and awareness of environmental justice is rising, the pollution gap between rich and poor communities remains and has even widened. Take the emission of toxic release inventory in the United States: people living in the poorest counties have seen a decrease in emissions of 18%, yet those in the richest counties had a 68% reduction in emissions (Kalnins and Dowell 2015).

Risk management and risk communication

Following risk assessment—which is evaluating the consequences of exposure to environmental agents—risk management becomes important. Risk management is a decision-making process of selecting and determining how to manage the identified environmental risks and how to implement the regulatory response (Commission on Risk Assessment and Risk Management 1997). This process can also help governments prioritize how they allocate resources to risks (Rocks et al. 2017).

However, in the real world, there is often a gap between risk levels, governmental priorities, and public interest (Commission on Risk Assessment and Risk Management 1997). Thus, understanding the risk perceived by the general public and properly communicating potential hazards to stakeholders can lead to more effective risk management (Commission on Risk Assessment and Risk Management 1997; Rocks et al. 2017). For environmental emergency scenarios, communication of risk to the general public should start as early as possible to ensure comprehensive understanding and prevent panic (Bol 2016).

Risk communication is the exchange of information about environmental risks among risk assessors, managers, news media, interested groups, and the general public (National Research Council 1989). An example is the concern over adverse health effects following the large-scale nuclear accident at the Fukushima Daiichi Nuclear Power Plant in Japan in March 2011. The first concern raised was about health risks to the local population due to radiation exposure. Although such risks were found to be limited (World Health Organization 2013), related information should have been delivered to residents in a timely and appropriate way to prevent anxiety and mistrust of the authorities.

In addition to reporting the level of toxic agents and the risk of developing disease, risk communication should also aim to prevent potential stigma from attaching to polluted areas. Development of a health literacy toolkit that translates scientific and medical jargon into terms understandable by the general population can help medical professionals answer people's questions and monitor their health (Murakami et al. 2017; Goto et al. 2018).

Another concern related to the Fukushima Daiichi event was food safety, both inside and outside the region, due to radioactive materials leaking from the nuclear plant. This also posed a challenge to international trade and public health in other countries. The general public have expressed concerns

about the indirect and long-term health risks from dietary exposure to contaminated food (Hasegawa et al. 2015; Cho et al. 2017). Right after the accident, the Japanese government set limits for radioactive elements and restricted the sale and distribution of food products from Fukushima and other areas with significant contamination. The immediate actions (e.g. announcing new guidelines) and timely communication (e.g. providing food safety education and disclosing information to the public) were key to relieving concerns about radiation residues in food products, promoting food safety, and securing food supply stability (Gilmour et al. 2016; Cho et al. 2017).

The precautionary principle

A key issue facing risk management is how to proceed in the presence of hazard data with limited or no evidence of human toxicity. Applying the precautionary principle while additional scientific information is being gathered is one approach. The precautionary principle was given impetus by the 1992 Rio Declaration on Environment and Development, which provided the following statement: 'In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation' (United Nations Environmental Programme 1992). The Rio Declaration forces the consideration of precautionary intervention but does not necessarily require such intervention. It includes qualifying language such as 'according to their capabilities' and 'cost-effective measures'. Furthermore, the triple negative notion—that the *absence* of rigorous proof of danger does *not* justify *in*action—is viewed by some as rather weak (World Commission on the Ethics of Scientific Knowledge and Technology 2005).

There are many variants of the precautionary principle, and extensive literature devoted to developing a more rigorous definition. To some, the precautionary principle is merely a means to build more public health protection into quantitative risk analysis, with additional prudent defaults and safety factors to protect at-risk populations and a further focus on uncertainty. To others, the precautionary principle is a new way of addressing environmental risk and dealing with complexity and uncertainty.

Its use is more likely to provide timely and preventive interventions (Kriebel and Tickner 2001; Martuzzi 2007). Some of the important approaches advocated by the precautionary principle, such as transparency and involvement of stakeholders, have also been frequently advocated under the rubric of risk assessment and management.

The United States banned the production of polychlorinated biphenyls (PCBs) in 1976, despite industry opposition, then and now, on the grounds of uncertain science. The continual decline in body burden of PCBs and dioxins has thus been accomplished based on regulatory decisions. Yet advancing the science needed for public health decision-making must remain a major goal, despite the usefulness of the precautionary principle (Foster et al. 2000; Goldstein and Carruth 2003, 2004; Grandjean et al. 2004).

The working definition of the precautionary principle proposed by UNESCO (see Box 7.4.7; italics in the original) includes the firm statement that actions based upon the precautionary principle should be subject to continuous analysis and review (World Commission on the Ethics of Scientific Knowledge and Technology 2005). A number of major concerns have been raised about the precautionary principle, for example, what does it add to standard public health concepts? Is it true that complex scientific questions are unsolvable and, if so, is the precautionary principle needed to promote action in the face of scientific uncertainty? In view of its alleged use to justify trade barriers, is it still possible to advocate the precautionary principle as an antidote to biased decision-making?

Box 7.4.7 Working definition of the precautionary principle

'When human activities may lead to morally unacceptable harm that is scientifically plausible but uncertain, actions shall be taken to avoid or diminish that harm. *Morally unacceptable harm* refers to harm to humans or the environment that is

- threatening to human life or health, or
- serious and effectively irreversible, or
- inequitable to present or future generations, or
- imposed without adequate consideration of the human rights of those affected.

The judgement of *plausibility* should be grounded in scientific analysis. Analysis should be ongoing so that chosen actions are subject to review. *Uncertainty* may apply to, but need not be limited to, causality or the bounds of the possible harm. *Actions* are interventions that are undertaken before harm occurs that seek to avoid or diminish the harm. Actions should be chosen that are

proportional to the seriousness of the potential harm, with consideration of their positive and negative consequences, and with an assessment of the moral implications of both action and inaction. The choice of action should be the result of a participatory process.'

The precautionary principle is said to be pertinent in situations where the scientific evidence is uncertain. One example is the management of the health and environmental risks of endocrine disruptors. This is particularly challenging due to the need to consider the interactive effects of multiple chemicals with a wide range of additive, synergistic, and antagonistic interactions (Kortenkamp 2007). A case study is shown in Box 7.4.8.

Box 7.4.8 The precautionary principle and bisphenol A

Worldwide, over 3 million tonnes of bisphenol A (BPA) are produced annually. BPA can be found in many consumer products. These include reusable water bottles, baby bottles, implantable medical devices, and dental sealants. BPA is also a component of epoxy resins, which are used to overlay the inside of food and beverage cans, in cardboard and papers used for food wrapping, in some plastic water pipes, and in paints and cigarette filters. Of concern is the fact that BPA leaches out from these consumer products, even under normal use conditions. The leaching increases under high temperatures, and with exposure to acidic or basic solutions.

Animal studies have shown that BPA may alter male and female reproductive tract development, the brain, and the mammary glands. In large-scale human population studies in various parts of the world, BPA has been detected in urine, blood, saliva, breast milk, and tissues and fluids associated with pregnancy at levels similar to those that have been shown to cause damage in animals. In a study of over 5,000 people in Canada, over 90% had detectable levels of BPA in urine, with a geometric mean concentration of 1.16 ng/mL (Bushnik et al. 2010). Health Canada has stated that precaution is warranted, since it is not possible to dismiss the potential harmful effects of BPA (Health Canada 2010). With this statement, Canada became the first country to declare BPA a health hazard, but additional regulatory action has yet to be taken (Vandenberg 2011).

Practical insight into the debate about the precautionary principle versus risk assessment can be found in the way the EU and other countries evaluate the safety of chemicals. The EU promulgated the REACH regulations, after much debate, with its proponents focusing on the precautionary principle as a rationale for the new legislation. REACH requires industry to develop data, assess risk, and provide information about virtually all chemicals in use, including constituents of product mixtures. No distinction is made

between newly developed chemicals or those long available in commerce—a contrast with the US Toxic Substances Control Act, whose weakness in this regard led to the inadequate testing of compounds such as the gasoline additive methyl tert-butyl ether (MTBE) before its inappropriate release into the environment (Erdal and Goldstein 2000).

The cost of implementing REACH is estimated at US$3–6 billion for obtaining data and registering compounds over the first 11 years. Risk assessment, based on both toxicity and exposure, will be used extensively throughout the process, including for setting priorities for data needs and making decisions on regulatory approaches. Unfortunately, there appears to be no uniform coordinated effort to develop the research where toxicological data is scant.

Unfortunately, the precautionary principle has been tainted through disagreements over application. The United States, Canada, and other countries disagreed with the EU on the extent of risk to health from consumption of hormone-treated beef or genetically modified foods. The EU's use of the precautionary principle to establish a stringent aflatoxin standard, to the detriment of exports of sub-Saharan countries, has been criticized as the misuse of public health principles for trade protectionism (Goldstein 2007). The risk of exposure to electromagnetic fields from the use of mobile phones is another contentious and confused issue, resulting in advice based on a mix of the precautionary principle and the scientific evidence.

The primary missing ingredient in the approach to ever more complex environmental challenges, including such broader issues as global warming, is a systems-based approach incorporating the best science and focusing on the most important questions. We need to have a more systematic and coordinated effort to respond to the challenges of fragmented national and international approaches to environmental issues that produce piecemeal efforts which may lead us to fall further behind in protecting public health and the environment.

Conclusion

Understanding the web of environmental cause and effect relations is an increasing challenge in an ever more connected world. Advances in toxicology, filtered through an appropriate appreciation of the optimal

approaches to analysing and presenting risks to an involved public, are crucial to protecting public health and the environment.

Risk perception and communication

Baruch Fischhoff and Tamar Krishnamurti

Public health depends on laypeople's ability to understand the health-related choices that they and their societies face. The study of risk perception examines that ability. The study of risk communication examines the processes that determine how well communications help (or hinder) their recipients. Although focused on decisions involving risk, such research necessarily considers potential benefits as well, if only the benefits that come from reducing risks (e.g. through medical treatments, lifestyle changes, or improved air quality). Communication is a two-way process. Without listening to people, it is impossible to understand what they know and value, as a foundation for providing relevant information in a comprehensible form. Here, we draw on basic research in decision science (behavioural decision research) to inform the specific challenges faced by public health researchers and practitioners.

The decision science approach is conceptually straightforward. First, analyse the decisions that people face, in sufficiently precise terms to identify the information most critical to their outcomes. Second, describe decision-makers' existing beliefs in terms comparable to the analysis. Third, develop communications that bridge the critical gaps between what people know and what they need to know. Next, evaluate the success of those communications. Repeat as necessary. These steps are interdependent. Descriptive research can reveal goals, obstacles, and capabilities that the analyses missed; communication failures can prompt additional descriptive research into decision-making processes. Evaluation is essential. One cannot expect to get it right the first time.

Effective communication requires four kinds of expertise: (a) subject matter specialists, for ensuring accuracy; (b) risk and decision analysts, for characterizing choices and identifying critical information; (c) social and behavioural scientists, for describing existing beliefs, values and capabilities,

and designing communications; and (d) communication practitioners and implementation scientists, for executing and evaluating sustainable programmes. The success of the enterprise depends on continuing two-way communication with audience members, as depicted in Figure 7.5.1, so that professionals understand their needs, they understand what the professionals are doing, and the process creates the personal ties needed for mutual trust.

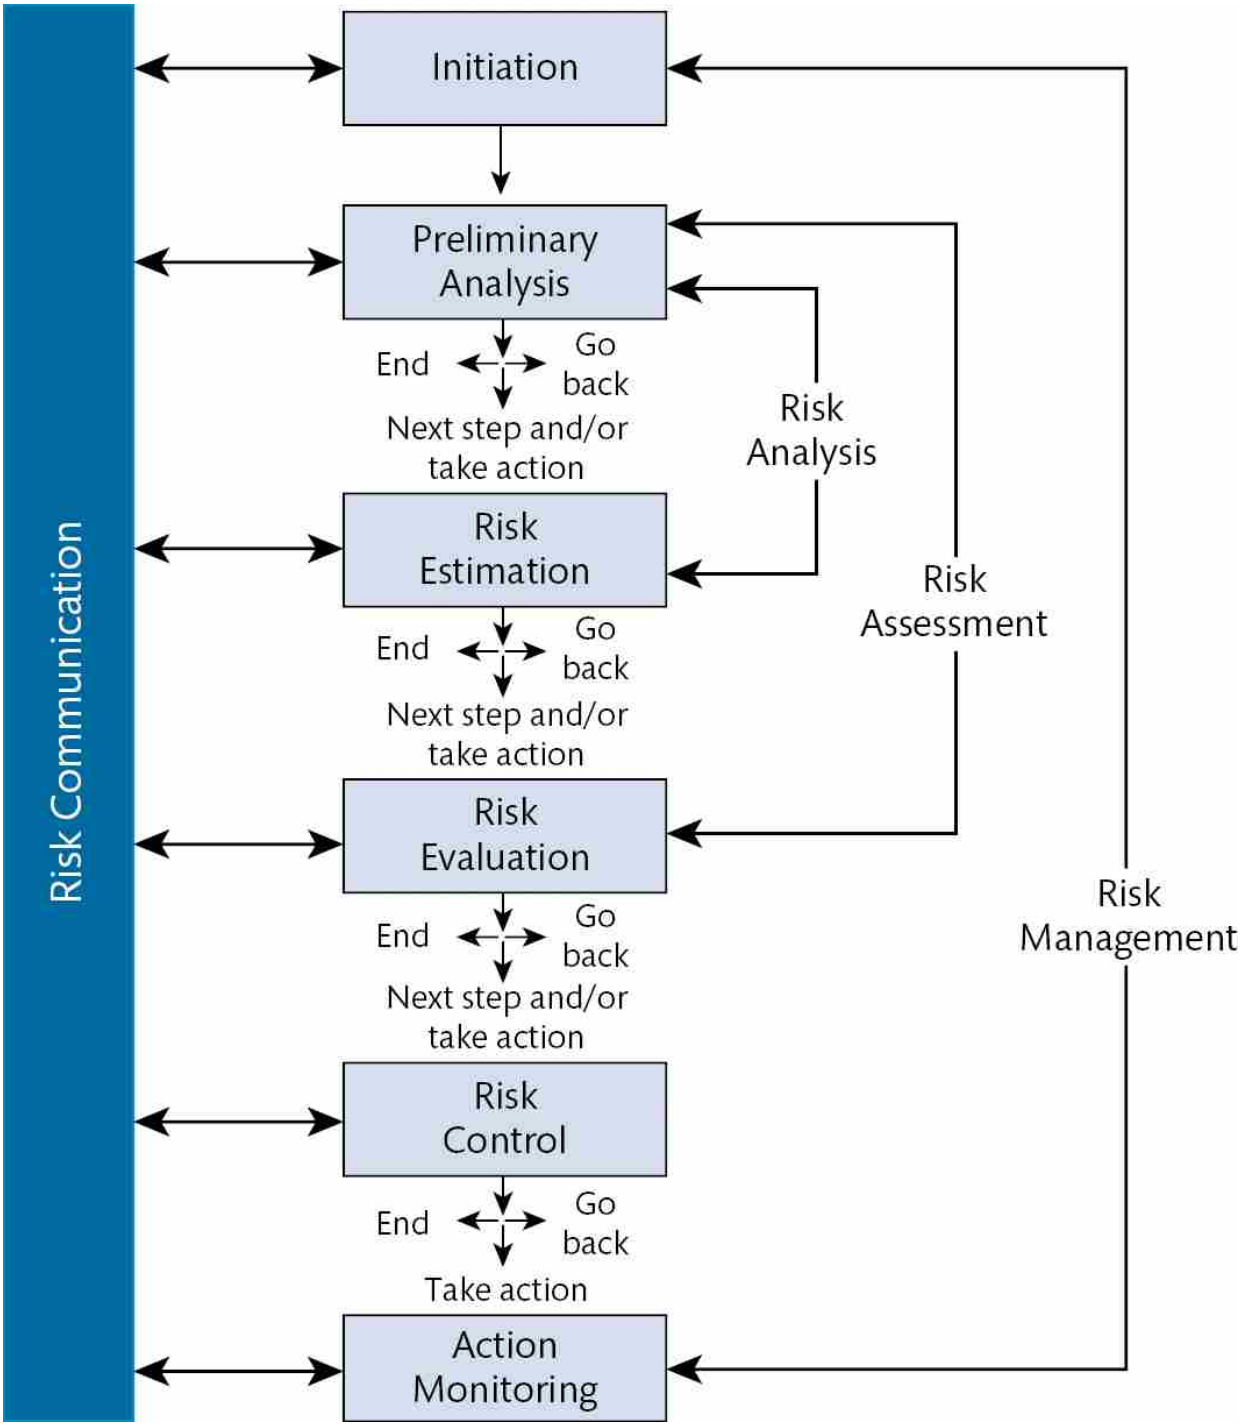

Fig. 7.5.1 Two-way communication.

Decision science provides guidance on two topics central to this endeavour. One is how to identify threats to risk-related decision-making and ways to overcome them. The second is how to measure communications' success. Without such evaluation, not only may

communications fail, but experts may come to doubt their audience's competence. If laypeople are held responsible for failing to learn from flawed communications, then they may be needlessly denied the opportunity for active participation in health decisions. One should no more release untested communications than untested pharmaceuticals. The chapter seeks to help experts help laypeople make wise health choices.

Introduction to risk perception and communication

Sound health risk decisions require understanding the risks and benefits of possible actions. Some choices are personal. They include whether to wear bicycle helmets and seat belts, whether to read and follow safety warnings, whether to buy and use condoms, and how to select and cook food. Other choices are public. They include whether to protest the siting of hazardous waste incinerators and halfway houses, whether to support fluoridation and 'green' candidates, and what topics to include in sex education (e.g. relationships as well as risks).

Sometimes, single choices have large effects (e.g. buying a safe car, taking a dangerous job, having a child). Sometimes, small effects accumulate over multiple choices (e.g. exercising, avoiding trans-fats, wearing seatbelts, using escort services, getting tattoos). Sometimes, health-related choices focus on health; sometimes, they do not (e.g. purchasing homes that require long commutes, choosing friends who exercise regularly, joining groups opposed to vaccination).

This chapter reviews the research base for assessing and improving individuals' understanding of the risks and possible benefits of health-related choices. Following convention, these pursuits are called *risk perception* and *risk communication*, respectively. Psychologists sometimes reserve the term 'perception' for direct physiological responses, using 'judgement' for their translation into deliberate actions.

Inaccurate judgements about risks can harm people. So can inaccurate beliefs about those judgements. If their decision-making ability is overestimated, people may face impossibly hard choices (e.g. among unfamiliar medical options, without adequate counselling). If their ability is underestimated, people may be needlessly denied the right to choose. As a result, the chapter assumes: (1) that descriptive statements about how people make decisions require supporting evidence and (2) that evaluative

statements about how well people make decisions require rigorous analysis of what they need to know. To these ends, the chapter emphasizes methodological safeguards against misguided assessments.

The next two sections present methods for assessing people's estimates of the size of risks and what they believe about the processes that create and control those risks. They are followed by sections on how to create and evaluate communications that address critical gaps in understanding. The concluding section considers the strategic importance of risk communication in public health.

The present chapter focuses on how to help people to be as informed as possible when making personal and public health decisions. Access to research on complementary social and emotional processes might begin with Breakwell (2014), and Slovic (2010), Our methodological focus recognizes that basic science has been disproportionately conducted in developed, Western countries—meaning that studies of what people believe and want should be repeated to capture local conditions (Medin et al. 2017). (Results related to how people process information might be more robust.) However, decision science methods should apply broadly, using experimental, survey, interview, and observational approaches to determine breadth and population distribution of beliefs, desires, and needs.

Quantitative assessment

Estimating risk magnitude

A common complaint among experts is that 'the public doesn't realize how small (or large) Risk X is'. There is empirical evidence demonstrating such biases (Slovic 2001). However, that evidence has often been collected in experimental settings designed to reveal biases, so that researchers can see just how they work. Such studies say little about how large or common biases are in everyday life. As a guide to interpreting and conducting studies that assess lay beliefs, we examine one widely cited study.

Participants

Lichtenstein et al. (1978) asked members of a civic group in Eugene, Oregon, to estimate the annual number of deaths in the United States from

30 causes. They chose causes that were familiar, well-defined, and for which public health statistics were available (e.g. botulism, tornadoes, motor vehicle accidents). They also elicited judgements in two ways that allowed comparing responses with those statistics. One of these *response modes* asked people to pick the more frequent of two paired causes of death (e.g. asthma, botulism) and then estimate the ratio of their frequencies. The second response mode asked people to estimate the number of deaths, after telling them the value for one cause (either electrocution or motor vehicle accidents) in order to give respondents a feeling for annual death rates—after pre-tests found that many people had little idea about what numbers to give. The results were typical of such studies.

Results

Judgements of the *relative* risk from different causes were similar however the question was asked, as though people have a sense of relative risk, which they express consistently even with such unfamiliar tasks.

Judgements of *absolute* risk, however, were affected by the procedure. People told about the 50,000 annual deaths from auto accidents gave higher estimates than did those told about the 1,000 annual deaths from electrocution. Thus, people have less feeling for absolute frequency, rendering them sensitive to implicit cues given by how questions are posed (Poulton 1989; Schwarz 1999).

Absolute risk judgements varied less than the corresponding statistical estimates. A substantive interpretation is that people do not realize just how large the differences are between life's big and small risks. A methodological interpretation is that these judgements were *anchored* in the initial values presented to participants (for electrocution or motor vehicle accidents). Because these values were in the middle of the range, participants overestimated small frequencies and underestimated large ones. That pattern might change with other anchors. For example, a lower anchor (e.g. botulism) should reduce (or eliminate) overestimation of small frequencies, while increasing the underestimation of large ones.

Both relative and absolute risk judgements seemed to reflect *availability bias*, whereby easily imagined causes of death (e.g. flood, homicide, tornadoes) seem disproportionately likely, whereas the opposite is true for 'quiet killers' (e.g. stroke, stomach cancer). Telling people about the possibility of availability bias did not help them to overcome it, as tracking frequency of events is so automatic that people do not realize how observations shape their perceptions.

Thus, some response patterns were affected by the procedure (e.g. absolute estimates) and some were not (e.g. relative risk judgements). A century-plus of psychophysics research (Poulton 1989) has identified many procedural details that can affect quantitative judgements, when people don't know quite what to say. Awareness of that research can be a valuable antidote to taking quantitative estimates too literally. Eliciting judgements in several ways can establish how big such context effects are, and how much they could affect decisions.

Evaluative standards

Risk judgements can be evaluated in terms of *consistency* or *accuracy*. Evaluating consistency means asking logically related questions and comparing the answers (e.g. do risk estimates increase with increases in the number of exposures or time period?). Evaluating accuracy means asking questions that can be compared to risk estimates. This requires greater precision than is common to many surveys.

The alternative to asking people about their beliefs is trying to infer them from their actions. For example, first-time gun sales often spike after mass shootings in the United States (Studdert et al. 2017). That common reaction could reflect fear of gun violence or of gun control. After the 9/11 attacks, some observers claimed that some Americans had increased their risk level by choosing to drive, rather than fly, citing historical risk statistics. However, at the time, no one knew if the historical statistics still applied or if those travellers assumed any additional risk voluntarily, weighing the cost and hassle of flying (once that became possible again). It is often hard to tell, by observation alone, what beliefs and preferences motivate decisions.

Probability judgements

Health decisions depend on the probability, and not just the possibility, of good or bad things happening (e.g. treatments working, side effects occurring). Although many experts are sceptical about how well people can use probabilities, the research shows a more complex picture (e.g. O'Hagan et al. 2006; Morgan 2014):

People interpret verbal quantifiers (e.g. likely) differently depending on the context (e.g. rare disease vs. rare sunny day), making it hard to know what they mean or infer (Budescu and Wallsten 1996).

People prefer to *receive* numeric probabilities, which provide more information, but to *provide* verbal ones, which involve less effort and accountability (Erev and Cohen 1990).

People can use well-designed numeric scales. For example, Woloshin et al. (1998) elicited very small probabilities with a scale that was linear from 1% to 100%, but had expanded 0–1% with a four-order log scale.

Numeric judgements often have good *construct validity*, in the sense of correlating sensibly with other variables. For example, in a nationally representative sample, teens giving higher probabilities of becoming pregnant also reported more sexual activity; teens giving higher probabilities of getting arrested also reported more neighbourhood violence.

Numeric judgements often have good predictive validity. For example, in that survey, teens who gave higher probabilities were more likely to get pregnant or arrested.

Biased numeric judgements may reflect misinformation, rather than difficulty with numbers, as when people underestimate their own probability of causing an accident because others' poor driving is more available to them or physicians fail to prescribe antidepressants as pregnancies progress (Yonkers et al. 2014), even though foetal risk dramatically diminishes after the first trimester.

Probability judgements can be deliberately biased, when people respond strategically. For example, Christensen-Szalanski and Bushyhead (1993) found that physicians overestimated the probability of pneumonia, fearing that unlikely cases might be neglected.

Transient emotions can affect judgements. For example, anger increases optimism, fear the opposite (Lerner and Keltner 2001), with effects large enough to tip close decisions.

Judgements of the probability of being correct are moderately correlated with how much people know. The result is *overconfidence* with hard questions (e.g. correct 55% of the time when 70% confident) and underconfidence with easy ones (e.g. correct 90% of the time when 80% confident).

Some numeric values are special. People like round numbers. When uncertain about their answer, they sometimes say 50 in the sense of 50–50,

rather than a numeric probability (Bruine de Bruin et al. 2000).
Probability judgement processes mature by middle adolescence. For example, teens are no more likely than adults to believe in their own invulnerability (Quadrel et al. 1993).
Some people use probabilities better than others; they also tend to be better at other judgement tasks and have better life outcomes (Mellers et al. 2015; Parker et al. 2018).
People who are low in numeracy and literacy can make probability judgements with carefully designed displays (e.g. icon arrays, pictographics; Hawley et al. 2008).
Clear, prompt feedback can improve how well people use probabilities (Lichtenstein and Fischhoff 1980; Mellers et al. 2015).
Experts are people, too, when forced to go beyond established knowledge and judge probabilities of uncertain events (O'Hagan et al. 2006).

Unless people provide numeric judgements, it is impossible to know how accurate their beliefs are and to tell, for example, whether public health communications have exaggerated fears of smoking (Viscusi 1992) and breast cancer (Black et al. 1995).

Defining risk

Studies like Lichtenstein et al. (1978) measure 'risk' perceptions, only if 'risk' means 'chance of death'. However, 'risk' has multiple meanings, even among experts (National Research Council 1996; Fischhoff and Kadvany 2011). It might include just deaths or also other outcomes, such as morbidity and trauma. Even if it includes just fatalities, it might be measured in probability of death, expected life years lost, deaths per person exposed, or per hour of exposure. Each definition entails an ethical position. For example, *probability of death* treats all deaths equally, whereas *life years lost* places extra weight on deaths of young people as they incur more lost years. In public health policy, that definition would direct resources to reducing injuries, which affect young people, relative to chronic illnesses, affecting older ones. Defining 'risk' to Include social and psychological costs would increase concern for alcohol and illegal drugs, which can ruin lives without ending them (Phillips et al. 2017).

Without a clear, shared definition of 'risk', people can unwittingly speak at cross purposes. One source of confusion is treating risk as a discrete

variable (deeming some activities as ‘risky’ and others as ‘safe’), rather than as a continuous one, requiring decision-makers to decide how much risk to tolerate. Calling something ‘risky’ could mean an unreasonable demand for zero risk, a shorthand for being ‘acceptable (given the benefits)’, or a call for invoking a *precautionary principle*, making it as too great to countenance (Löfstedt et al. 2002).

Dimensions of risk

One early risk perception study asked experts and laypeople to estimate the ‘risk of death’ from 30 activities and technologies (Slovic 1987), then correlated their judgements with statistical estimates of annual fatalities. That correlation was stronger for experts than for laypeople. However, when asked to estimate ‘fatalities in an average year’, experts and laypeople responded similarly. Comparing those judgements suggested that lay respondents interpreted ‘risk of death’ as including the catastrophic potential of non-average years. If so, then experts and laypeople agreed about routine risks (for which the science is often good), but disagreed about possible anomalies (for which the science is naturally weaker). Thus, when experts and laypeople disagree about risks, they might be seeing the facts differently or looking at different facts, relevant to their definition of ‘risk’.

Considering catastrophic potential could reflect one of (at least) two ethical concerns. One is caring more about lives lost at once, rather than lost individually. The second is caring more about uncertain risks, poorly enough understood that catastrophes are possible (Slovic 1987). Beginning with Starr (1969), many features, like uncertainty and catastrophic potential, have been proposed as affecting definitions of risk (Fischhoff and Kadvany 2011). One way to reduce that set to manageable size is to examine correlations between the features. Figure 7.5.2 shows results from a first study. It finds two *dimensions* of risk. The vertical dimension reflects the fact that hazards seen as new also tend to be seen as unknown, involuntary, and with delayed effects. The horizontal dimension reflects that fact that hazards with catastrophic potential also tend to evoke a feeling of dread. The factors labelled *unknown* and *dread*, respectively, might be seen as capturing cognitive and emotional aspects of people’s concern. Many studies following this ‘psychometric paradigm’ have found roughly similar dimensions, using differing elicitation modes, scaling techniques, items, and participants (Slovic 2001; Glassman-Fox and Weber 2016). Where hazards fall in the

space correlates with attitudes towards them, such as how stringently they should be regulated.

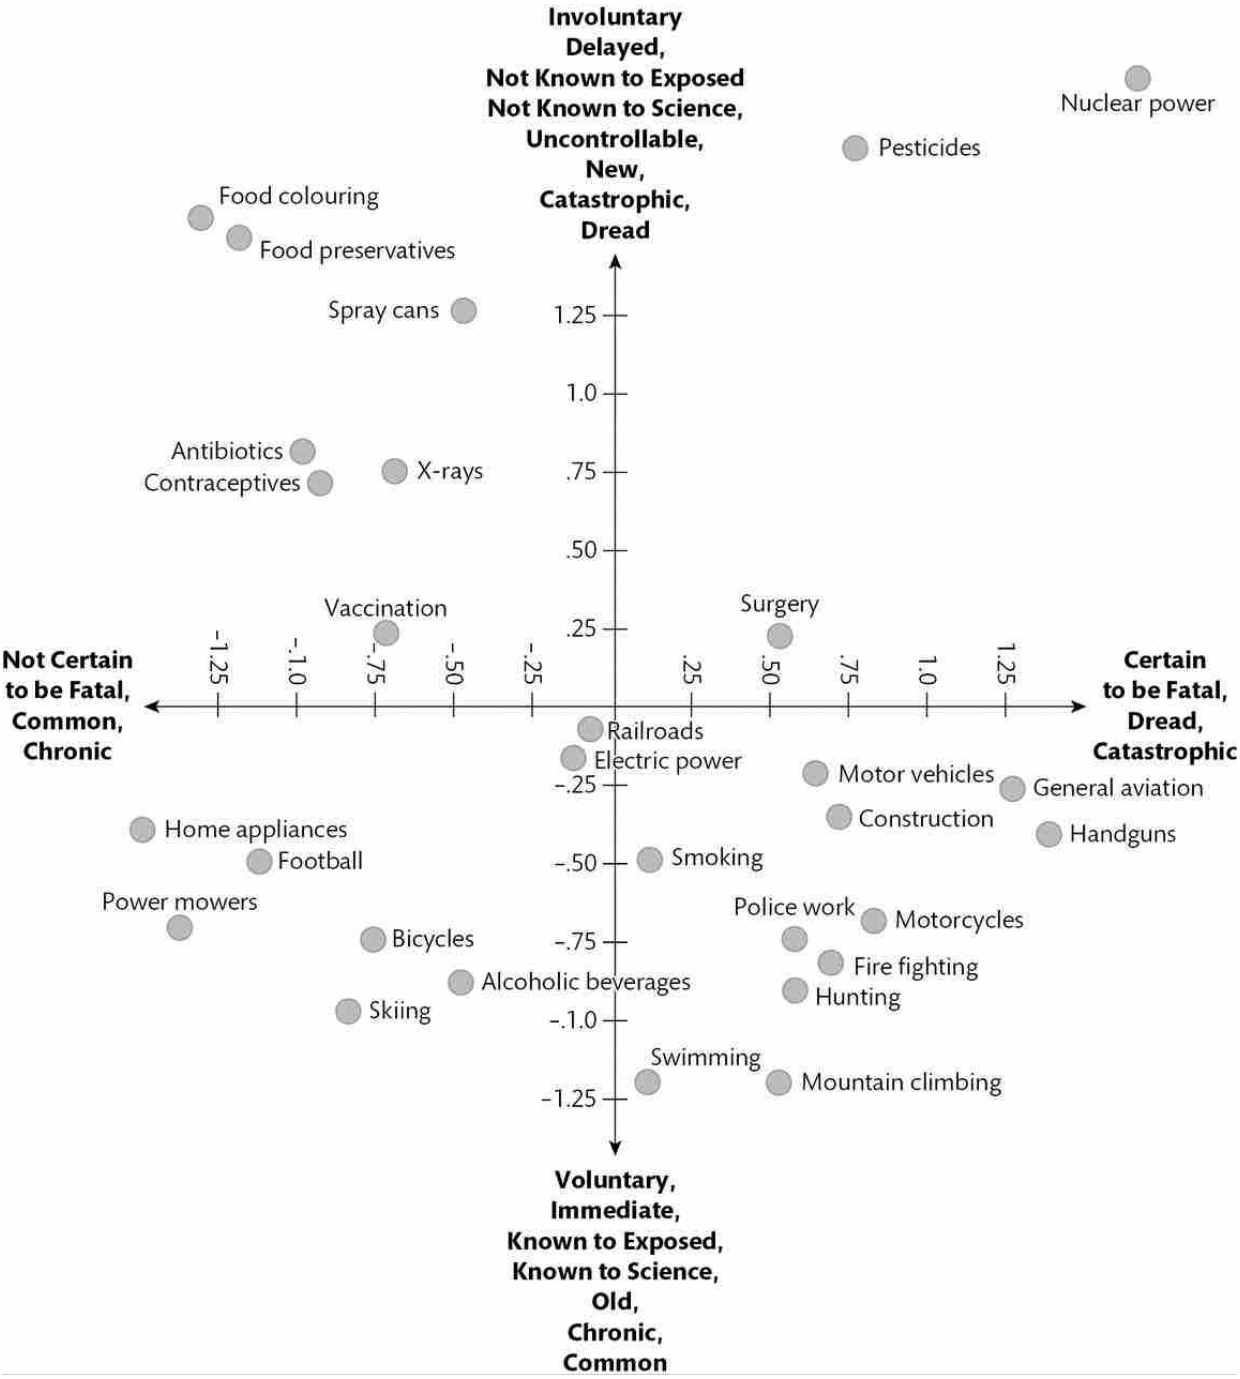

Fig. 7.5.2 Dimensions of risk.

Comparing risks

The multidimensionality of ‘risk’ belies simple comparisons, when people wish to determine which risks are most important or whether risks are being managed consistently. For example, concern about terrorism might be exaggerated given the number of fatalities, but not given its catastrophic potential or the sense of dread that it can induce. Thus, any comparison requires agreement on what ‘risk’ means.

One ambitious effort to develop socially acceptable definitions of risk was undertaken by the US Environmental Protection Agency (USEPA 1993). Following consultation with its staff and Scientific Advisory Board, it conducted or facilitated dozens of regional, state, and national ‘risk-ranking exercises’, in which participants identified the dimensions important to them, then deliberated priorities, supported by technical staff providing needed evidence. Letting participants choose the dimensions made these exercises more relevant to their needs, but reduced comparability across exercises. Florig et al. (2001) developed a method for standardizing such comparisons, based on the risk dimensions research. The UK government employed a variant (HM Treasury 2005).

The US Food and Drug Administration’s Voice of the Patient initiative (https://www.fda.gov/forindustry/userfees/prescriptiondruguserfee/ucm368342.htm) created a structured methodology for soliciting input from diverse stakeholders for determining the features that it should consider when evaluating the risks and benefits of proposed treatments. The US National Institute of Health’s PROMIS initiative (http://www.healthmeasures.net/explore-measurement-systems/promis) offers a standard set of (free) patient-reported outcomes measures that could be used to characterize risks. The related PROPr project has developed ways to weight the outcomes that decision-makers choose to consider (Dewitt et al. 2018).

Qualitative assessment

Event definitions

Once adequately defined, ‘risk’ can be estimated. With sexually transmitted infections (or pregnancy), that might mean specifying such details as

frequency and timing of intercourse, contraceptives used, and partners' physical state. Two experts with different definitions may see the same data and produce different estimates. So might laypeople asked for risk perceptions, but forced to guess exactly what is meant. For example, a prominent national survey asked: 'How likely do you think it is that a person will get the AIDS virus from sharing plates, forks, or glasses with someone who has AIDS?' After answering this question, US college students were asked what they had inferred about the kind and amount of sharing. Most agreed about the kind, with 82% selecting 'sharing during a meal' from a set of options. However, they disagreed about the frequency, with 39% selecting 'a single occasion', 20% 'several occasions', 28% 'routinely', and 12% uncertain (Fischhoff 1996). Respondents making different assumptions were, in effect, answering different questions, whose meaning researchers must guess, if they are to offer any conclusions about lay risk perceptions.

Laypeople are, similarly, left guessing when experts communicate about risks ambiguously. For example, McIntyre and West (1992) found that teens knew that 'safe sex' was important, but disagreed about what it entailed. Downs et al. (2004) found that teens interpret 'it can only take once' as meaning that they will get pregnant after having sex once. If they do not, some infer that they are infertile, encouraging unsafe sex. The best strategy for ensuring that people are talking about the same thing is empirical study, as discussed next.

Supplying details

The details that people infer, when given ambiguous and incomplete risk questions or messages, reveal their intuitive theories. For example, bleeding or fluid loss during pregnancy can have serious health implications. However, some spotting or light bleeding is common and normal. Women who experience spotting may worry unduly whereas women who have experienced spotting in the past with no ill-effects, may not realize the significance of heavier bleeding. They might attribute normal, light bleeding in pregnancy to menstruation, leading them to misattribute abnormal heavier bleeding to a routine reproductive process. Krishnamurti et al. (2017) explicitly addressed this incomplete mental model with a real-time symptom tracker designed to help women distinguish harmless from harmful bleeding.

Cumulative risk—a case in point

There is no full substitute for directly studying the beliefs that people bring to and take away from communications, especially when they come from backgrounds different than those of the communicators (Medin et al. 2017). However, the research literature provides a basis for anticipating those beliefs (Fischhoff et al. 2011). For example, unrealistic optimism is so widespread that one can assume that people see themselves as facing less risk than other people, whenever some personal control seems feasible (Shepherd et al. 2015).

Just as teens' insensitivity to the amount of sex, when judging STI risks, reflects a well-known insensitivity to how small risks accumulate over repeated exposures, people cannot be expected to infer the cumulative accident risk from driving without a seat belt (Slovic et al. 1978), or the pregnancy risk from having sex without effective contraceptives (Shaklee and Fischhoff 1990). A corollary is not realizing the cumulative impact of small differences in single-exposure risks (e.g. slightly better contraceptives, wearing a seat belt). For example, college students estimated the probability of male-to-female HIV transmission, as 10% in one case of protected sex and 25% in 100 cases. Given then-current estimates, the former was much too high and the latter fairly accurate. That inconsistency was only revealed by asking about both. The more relevant question for predicting behaviour depends on whether people think about single or multiple exposures (Fischhoff 1996). People similarly underestimate exponential growth, meaning that they may be able to estimate a disease's basic reproduction number (R0) without appreciating how quickly it will spread (Fischhoff et al. 2018).

Mental models of risk processes

The role of mental models

As mentioned, when people lack explicit information about the magnitude of a risk (or benefit), they must infer it. Judgement heuristics, like availability, provide one class of inferential rules for deriving specific estimates from general knowledge. A second class draws on individuals' *mental models* of the general processes that create and control risks. Mental models have a long history in psychology, having been studied for topics as diverse as how

people understand physical processes, international tensions, complex equipment, energy conservation, climate change, interpersonal relations, and drug effects (Ericsson and Simon 1993; Morgan et al. 2001). They are how people navigate their world.

Mental models can fail people when their premises are faulty or incomplete, or when inferential processes are flawed. For example, not realizing how quickly the risks of pregnancy and STIs accumulate could make other knowledge seem irrelevant. In a study of domestic radon, Bostrom et al. (1992) found that people often knew that it was a colourless, odourless, radioactive gas. However, they overestimated the risks and underestimated the opportunities for remediation, because they thought that radioactivity meant permanent contamination—not knowing that the radon by-products (or 'progeny') have short half-lives. As a result, once radon intrusions stop, the problem disappears. Yet, while it persists, rapid decay means rapid energy release. Homeowners unaware of these facts might reasonably decide not to test for radon—the problem doesn't seem urgent and there is nothing to do anyway if they find it.

Morgan et al. (2001) offer a general approach appropriate to studying mental models for complex, uncertain processes, like those of many public health risks. It begins by creating a formal (or 'expert') model, summarizing relevant scientific knowledge, with enough precision to compute quantitative predictions, were its data needs met (Fischhoff et al. 2006). A common formalism is the influence diagram, a directed graph with nodes, representing variables, and connecting arrows, representing relationships between them.

The research continues with open-ended, one-on-one interviews, structured around the model, eliciting lay beliefs in their intuitive formulation. Those 'mental model' interviews begin with general questions, asking respondents what they believe about the topic, then to elaborate on each issue that they raise. The tone is non-judgemental, seeking to understand, not evaluate respondents' perspectives. After exhausting responses to general questions, interviewers ask increasingly pointed ones, starting with general processes (e.g. exposure, effects, mitigation), and proceeding to specific issues (e.g. 'How does the amount of sex [or number of partners] affect HIV risk?'; 'What does "safe sex" mean?'). A variant has people think aloud while sorting photographs by their relevance, hoping for insights into topics that were otherwise missed. For example, seeing a

supermarket produce section prompted some respondents to say that radon might contaminate plants (Bostrom et al. 1992). The interviews continue until no new material emerges, achieving thematic saturation.

Once transcribed, interviews are coded into the formal model, adding new elements raised by respondents, marked as either misunderstandings or lay expertise (e.g. how equipment really works). The precision of the formal model typically allows reliable coding. Once mapped, lay beliefs can be analysed in terms of their accuracy, relevance, and specificity. For example, Bostrom et al. (1992) found that most respondents, drawn from civic groups, knew that radon is a gas (88%), which concentrates indoors (92%), is detectable with a test kit (96%), comes from underground (83%), and can cause cancer (63%). However, many believed erroneously that radon affects plants (58%), contaminates blood (38%), and causes breast cancer (29%). Few (8%) mentioned that radon decays. The interviews led to a structured survey suited to assessing the prevalence of beliefs in larger samples, with questions having ecological validity, in the sense of sampling the key topics in the formal model (Bruine de Bruin et al. 2007).

This overall approach has been successfully applied in numerous health contexts including STIs, sexual assault, emergency contraception use, Lyme disease, falls, breast cancer, vaccination, and infectious disease, as well as topics in many other domains, ranging from wireless technologies to nuclear energy sources in space (Fischhoff 1992; Morgan et al. 2001; Krishnamurti et al. 2008; Downs et al. 2008; Krishnamurti et al. 2012).

From risk beliefs to risk decisions

The adequacy of risk perceptions depends on the decisions that depend on them. Some decisions require precise estimates, others just a rough idea. For example, von Winterfeldt and Edwards (1986) showed that many decisions with continuous options (e.g. invest $X) are insensitive to the precise values assigned to the probabilities and utilities of possible outcomes. Dawes et al. (1989) showed that choices with discrete options (e.g. choosing graduate candidates) are often insensitive to exactly how predictors are weighted, meaning that simple linear (weighted-sum) models may do as well as more complicated ones. That result has good news for researchers hoping to predict behaviour. They should have some success with any model that includes the issues that matter to people or variables correlated with them. It

has bad news for researchers hoping to explain or change behaviour. Many models with different variables, implying different psychological processes, will have similar predictive success. As a result, one cannot tell which explains the predicted behaviour. The health-belief model is such weighted-sum model. It structures diverse topics in common terms, but must be supplemented by studies showing how people think about and respond to each part of their world. The greater the social distance between the experts and the public, the more important such studies become—lest experts miss options, uncertainties, or outcomes that occupy lay decision-makers, but would never occur to them, or vice versa.

As with any conversation, eliciting health beliefs and attitudes requires posing questions that people can answer in ways that are useful to the researcher. Because structured surveys offer limited feedback on differences on how respondents conceptualize a domain, there is no substitute for including open-ended procedures that allow people to express themselves in their own terms. For example, Beyth-Marom et al. (1993) found that teens think about the possible consequences of risky decisions (e.g. drinking and driving, smoking marijuana, skipping school) differently when framed in terms of doing and not doing them, even though the two are complementary actions. In that study, thinking about accepting risky options produced more consequences (suggesting that action is more evocative than inaction), a higher ratio of bad to good consequences (suggesting that action makes risks more available), and fewer references to social consequences (suggesting that social pressure is more salient when resisting temptation than when yielding to it). When participants were asked about making choices repeatedly, rather than just once, they often produced different consequences (e.g. repeatedly ‘accepting an offer to smoke marijuana at a party’ evoked more mentions of social reactions than did thinking about doing it once). Parents of the teens cited similar outcomes, except for more often mentioning long-term consequences (e.g. ruining career prospects). Thus, if parents and teens see these choices differently, it is not because they see different possible outcomes, but because they disagree about how likely and important those outcomes are. Such differences would be hidden with structured surveys that elicit ratings of fixed consequences, framed in just one way.

In a study imposing even less structure, teens chose difficult personal decisions, which they described in their own words (Fischhoff 1996). These

descriptions were coded by content (which choices are on teens' minds) and structure (how they are formulated). For example, these teens never mentioned decisions about drinking and driving, but often described decisions about drinking, suggesting that the latter decisions are a better focus for interventions. These teens typically focused on a single option (e.g. whether to attend a party with drinking), suggesting the value of helping teens to feel that they have options and to create attractive ones (e.g. socially acceptable ways to avoid excess alcohol). Seeing different ways to accept and reject risks should also reduce insensitivity to opportunity costs (foregone benefits) due to neglecting less visible options (Thaler 1991). For example, the direct risks of vaccinating children can loom much larger than the indirect risks of not vaccinating them (Ritov and Baron 1990).

Different methods for eliciting decision-makers' perspective have different, often complementary strengths and weaknesses (Ericsson and Simon 1993). Structured methods (e.g. surveys) allow efficient, readily analysed data collection, but increase the risk of miscommunication between researchers and respondents. Open-ended methods (e.g. mental models interviews) hear whatever is on respondents' minds, but increase the risk of interviewers sending non-verbal cues that influence what is said. Combined methods can provide rounded pictures, especially when grounded in shared formal analyses of the decision. One method that is common in commercial research, but rare in scientific studies, is focus groups. Indeed, their inventor, Robert Merton (1987) rejected them as sources of evidence (rather than just ideas), given the unnatural discourse of even well-moderated group. He preferred *focused interviews*, akin to mental models interviews, designed to hear individuals' views in depth.

Creating communications

Selecting information

Communication design begins by selecting content. The gold standard is a normative analysis, identifying the information most relevant to the choices that the communication is meant to inform (Fischhoff 2013). In practice, though, the content-selection process is often ad hoc, with experts intuiting 'what people ought to know'. That process can run afoul of the 'common knowledge effect', whereby people exaggerate how much goes without

saying, hence fail to provide essential details (Nickerson 1999). Poorly selected information can waste recipients' time, repeat relevant content, bury facts that people need to know among ones that are nice to know, and erode recipients' faith by showing insensitivity to their needs. It can also undermine experts' faith in their audience, if they fail to realize why their messages have missed the mark or asked recipients to do the impossible (Fischhoff 2011).

The logic of setting information priorities is straightforward: first provide the facts that will have the greatest impact, if properly understood. One place where information can overwhelm recipients is with informed consent procedures for medical treatments or trials. Merz et al. (1993) demonstrate a prioritization procedure using 'value of information analysis' (von Winterfeldt and Edwards 1986), finding that few of the many potential risks of carotid endarterectomy should matter to many patients. Krishnamurti and Argo (2016) demonstrated and validated another procedure, asking potential participants to identify the information that they most want to know. Although nothing should be hidden, communications should be sure to get the few key facts across.

At times, people face no specific choice, but just want to understand processes that could pose many decisions (e.g. new diseases, food-borne illnesses). The same logic of prioritization applies. Communications should focus on information that would be most useful for predicting the most important events (e.g. critical health signs, key factors in food safety). That information completes the mental models needed to monitor the environment, generate options, and follow discussions (Morgan et al. 2001). For example, Downs et al. (2004) found that most teens knew enough about HIV/AIDS to focus communications on a few critical gaps, such as how risks mount through repeated exposure and how hard it is for sexual partners to self-diagnose their own disease status.

An essential part of the content of any communication is the strength of the evidence supporting it (O'Hagan et al. 2006; Politi et al. 2007). Campbell (2011) shows ways to represent uncertainty graphically. Schwartz and Woloshin (2013) show how to describe the data quality (e.g. the length, size, and quality of clinical trials). Funtowicz and Ravetz (1990) show how to characterize the quality of the underlying science, including its *pedigree* (e.g. how well empirical patterns are supported by theory). Fortney (1988) found that oral contraceptives may increase a non-smoking woman's life

expectancy by up to 4 days and decrease it by up to 80 days, drawing on a research base so large that no conceivable study could materially change those bounds.

Formatting information

Once selected, information must be presented. There are many summaries of the relevant research (e.g. Wogalter 2006; Fischhoff et al. 2011). They note, for example, that comprehension improves when the text: (1) has a clear structure, corresponding to recipients' intuitive representation; (2) has a clear information hierarchy; and (3) provides *adjunct aids*, such as highlighting, advanced organizers (showing what to expect), and summaries.

However, even scientifically established design principles provide but a point of departure for communication design. Although better 'best guesses' than mere intuition, their success in any specific application is an empirical question. Standard usability testing procedures include seeing how long users take to find needed information, how often they reach the wrong information, and how often they realize that (Wogalter 2006). When there is variability in search patterns, designers need to decide which users' needs are most pressing. In a demonstration study, Riley et al. (2001) showed how users of dangerous consumer product (methylene chloride-based paint stripper) require widely varying efforts to reach safety information with different labels, then on the market. With some brands, they might not reach it at all.

Over the past 20 years, technology-based risk communications have become an integral part of public health (Eysenbach 2000). Increasingly, lay people and healthcare providers are turning to social media and digital health information technologies (e.g. patient and provider portals, weblogs, instant messaging platforms, social networks, and electronic consent) to monitor and share health risk information. There are currently over 300,000 commercially available mobile health apps for smartphones. These new platforms for health information exchange have great promise. Information can be presented in multiple non-text formats, making it more accessible to users with special needs and learning styles. Their potential for dynamic, interactive displays could allow tailoring information, targeting its content or format based on background knowledge, literacy, or numeracy. Increasingly ubiquitous access to the internet and smartphones makes it possible to reach

wider, more geographically diverse audiences. Predictive modelling of risk behaviour has the potential to further target communications. In a systematic review of social media use for health communication, Moorhead et al. (2013) also notes the data security risks with such communications.

Mohan et al. (2017) report a randomized controlled trial finding that online ‘serious game’ training conveyed risk information to emergency department physicians more effectively that conventional text-based training. To date, though, few of the many online applications have any published empirical evaluations. Each poses challenges of User-Interface (UI) and User-Experience (UX) design. The former focuses on the visual content and interactive elements; the latter focuses on the user’s enjoyment and engagement. Successful design can be informed by basic research on UI and UX. However, it still needs iterative testing with potential users, under conditions approaching actual use. One particular design risk is sacrificing effectiveness (and even accuracy) in pursuit of increased engagement. A second risk is that the increased the bandwidth demands of more engaging designs will disenfranchise those with limited access.

Evaluating communications

One should no more release an untested health communication than an untested drug. Indeed, communications are part of any medical product or procedure, affecting when it is chosen, how it is used, and whether problems are noticed in time to be remedied and reported. Arguably, evidence about such communications should be part of the submissions when products face regulatory approval. One standard for such evaluations to meet is that:

A communication is *adequate* if it:

Includes the information that recipients need, in order to make their decisions.
Affords them ready access to that information, given their normal search patterns.
Allows them to comprehend that information, with a reasonable effort.

Applying these tests requires evidence. Knowing what information people need requires learning their goals. Knowing whether people can find the information that is there requires observing how they search. Knowing how

much they comprehend requires seeing how well they have mastered the content.

Publication-quality evaluation requires resources and the training acquired by implementation researchers. However, simple forms of evaluation are within the reach of any communicator. In the US Food and Drug Administration *Communicating Risks and Benefits: An Evidence-Based User's Guide* (Fischhoff et al. 2011), each chapter ends with a section on how to conduct evaluations at no cost, small cost, or cost commensurate with the health, political, and economic stakes riding on effective communication. Central to any evaluation is listening, without presuming to know recipients' goals, beliefs, uncertainties, emotions, or modes of expression. In order to identify individuals' information needs, one can ask how they see the risks in their lives. In order to see how easily people can access information, one can watch as they search for it (e.g. online, in drafts; Downs et al. 2008). In order to assess a communication's comprehensibility, one can ask people to recall it, paraphrase it, make inferences from it, or create scenarios using it (Bruine de Bruin et al. 2007).

These are structured ways of talking about technical topics of mutual interest. As with any successful conversation, they must signal mutual respect. That means being able to hear unexpected responses. Even a few open-ended, one-on-one interviews might reveal incomprehensible or offensive material, or prompt questions about omissions. It also means framing those formative evaluations as testing the message, not its potential recipients. If they have not learned facts that matter to them, then the message must not have gotten that information across. Only when the resources of scientific communication have been exhausted should it be assumed that laypeople cannot learn what they need. The stakes riding on lay decision-making should justify that investment and humility. Amateurish communications can be worse than nothing, holding recipients responsible, or denying them the right, for decision-making, without giving them a fair chance.

The science of communication can guide *persuasive communications*, designed to induce behaviour that follows the communicators' wishes; *non-persuasive communications*, designed to help people make independent choices; and the *libertarian paternalist* hybrid where tasks are framed so that people voluntarily make decisions that someone has determined is 'for their own good' (Thaler and Sunstein 2009). Without studying people's goals,

however, one risks imposing experts' views on them. For example, Bostrom et al. (1992) found people who refused to follow communications that advocated testing for radon because they wanted to avoid creating evidence that could complicate selling their homes. Fischhoff (1992) describes the conflicting advice on reducing the risk of sexual assault, reflecting differences in experts' beliefs about women's (goals and the effectiveness of defence strategies). Reasonable individuals may 'defeat' safety measures by gaining more benefit from a product (e.g. driving faster with cars that handle better), frustrating experts concerned solely with safety.

Managing communication processes

Accomplishing these tasks requires four kinds of expertise:

Subject matter experts, who can identify the processes that create and control risks (and benefits).
Analysts, who can estimate the risks (and benefits) most pertinent to decision-makers.
Behavioural scientists, who can assess decision-makers' beliefs and goals, guide a communication's design, and evaluate its success.
Practitioners, who can create communication products and channels, for getting messages to audiences and obtaining feedback from them.

The work of these experts must be coordinated, so that they play appropriate roles. For example, behavioural scientists should not revise text, in an effort to improve its comprehensibility, without having subject matter experts check that the content is still accurate. Subject matter experts should not slant the facts according to their pet theories of how alarmed or calmed the public needs to be. Practitioners should not 'spin' health facts, the way that they might try to manipulate political agendas.

As noted, it is critical to involve target audience members in message and channel development. In the US, the Patient Centered Outcomes Research Institute (PCORI) was established to fund health research guided by the patients whom that research aims to serve (https://www.pcori.org/). It placed target audience involvement as central to its mission, starting from determining where better risk communication was critical, through to design and dissemination.

Figure 7.5.1 depicts the kind of two-communication needed to ensure that public health experts know how members of the public view their decisions and keep them informed of their actions. Creating such structured processes is a task for communication practitioners. They may need, for example, to interest members of the general public in topics far outside their current concerns, ascertain whether interest groups actually speak on behalf of their claimed constituencies, or empower those who might otherwise be neglected.

Conclusion

Effective risk communication is essential to health decision-making. Without it, individuals are denied the best possible chance of making sound choices —before, during, and after problems arise. As a result, they may suffer avoidable injury, while incurring the insult of feeling that they have failed to protect themselves or their loved ones. They may also feel anger at the experts have let them down, by not creating needed information and disseminating it in a timely, comprehensible way. As a result, communication must be central to how public health risks are studied and managed. It cannot be just an afterthought, letting the public know what the experts have learned or decided on its behalf. As depicted in Figure 7.5.1, it requires continuing, two-way communication.

This chapter has focused on general methods for assessing and addressing risk communication needs. It has avoided sweeping generalizations about what ‘people do’, ‘people believe’, and ‘people want’ That is because critical details vary across risk decisions and decision-makers. Responsive communication requires attending to the details of individuals’ lives and decisions. The basic science of risk perception and communication presented here could support research programmes dedicated to communicating the science presented in many chapters in the *Oxford Textbook of Public Health*, ensuring that the public gets full value from that science. Although the subject matter of each such research programme would be distinct, all could draw on the same basic research and methods. Given a well-characterized decision or risk, it is relatively straightforward, if technically demanding, to assess risk perceptions. If decision-makers’ risk (and benefit) perceptions have been measured well, then their choices can often be roughly predicted with simple linear models (Dawes et al. 1989). More precise prediction

requires more detailed understanding of the cognitive processes and mental models shaping these beliefs, and of the emotional, social, and economic factors impinging on the decision.

Meeting the challenge of effective risk communication requires coordinating four kinds of experts: subject matter specialists, analysts, behavioural scientists, and communication practitioners. Assembling such teams requires strategic leadership, which sees communication as essential to the public health mission. Communication research is inexpensive, relative to the stakes riding on sound decision-making, for individuals and for the public health organizations meant to serve them. Thus, there is no good reason not to assess risk perceptions and evaluate risk communications, drawing on the science summarized here. Such a scientific approach to risk communication would, for example, avoid the known pitfalls of ignoring the multidimensional character of 'risk', the problems with verbal quantifiers, or the need to help people see how risks mount up through repeated exposure. With the novel, complex, uncertain, fateful issues that can arise with health risk decisions, one cannot trust to intuition, when trying to meet decision-makers' needs.

Better risk communication should help recipients to make better decisions. However, it need not make their decisions easier, if it places hard choices in stark relief. Nor need it make communicators' lives easier, as recipients may discover bona fide disagreements. However, it should avoid needless misunderstanding, leading to fewer but better conflicts.

ACKNOWLEDGEMENT

The preparation of this chapter was supported by the Center for Climate and Energy Decision Making (SES-0949710) through a cooperative agreement between the National Science Foundation and Carnegie Mellon University and the Swedish Foundation for Humanities and Social Sciences and by an institutional training award from the NIH (KL2TR001856). The views expressed are the authors'.

7.6

Urbanization and health

Jason Corburn

Introduction

The majority of the world's population (4.2 billion) are now living in cities and municipal regions. According to the UN, 55% of the world was living in cities in 2018 and over 68% were expected to live in urban areas by 2050 (UN 2018). Urbanization is a dynamic and evolving physical, social and economic transformation that shapes the health and well-being of populations living in cities and around the world. City living can be healthy, since they can offer more population groups the health benefits of life-supporting infrastructure such as clean water and sanitation, education, and social services, as well as greater cultural, religious, and political expression and freedoms (Dye 2008). This holds true in both rich and poor cities of the global North and South. Thus, where we live, learn, work, and play, sometime referred to as our postal code, can matter as much or more than our genetic code for determining whether one will get sick, suffer unnecessarily, and even die prematurely.

Yet, not everyone living in cities can take advantage of the urban resources that can promote well-being. The increasing number of the urban poor and socially marginalized often experience health inequities, or differences in access to health-promoting resources that are unnecessary, avoidable, and unfair. As the UN Habitat and World Health Organization (WHO) stated in their 2010 report, *Hidden Cities: Unmasking and Overcoming Health Inequities in Urban Settings*:

> Health inequities are the result of the circumstances in which people grow, live, work and age, and the health systems they can access, which in turn are shaped by broader political, social and economic forces. They are not distributed randomly, but rather show a consistent pattern across the population, often by socioeconomic status or geographical location. No city—large or small, rich or poor, east or west, north or south—has been shown to be immune to the problem of health inequity. (WHO and UN Habitat 2010)

Importantly, the almost 1 billion now living in urban slums, informal settlements, or as 'pavement dwellers' in marginalized situations often have the worst health outcomes of all urban residents and their health is frequently worse than populations living in rural poverty (Lilford et al. 2017). The urban poor often experience inadequate housing and sanitation, lack of running water, poor or undernutrition, overcrowding, indoor and outdoor pollution, violence, limited access to healthcare, increased vulnerability to climatic events such as flooding and drought, and lack political power to influence policy decisions that can change their living conditions (Friel et al. 2011).

The links between global urbanization, inequities, and human well-being have been recognized by recent global agendas. The 2016 WHO/UN Habitat *Global Report on Urban Health* noted that national level wealth does not equate to health at the city level, conditions for health vary widely within the same city, and that cities must adopt a multisectoral response to promote health equity (WHO and UN Habitat 2016). The 2016 United Nations Conference on Housing and Sustainability (Habitat III) in Quito, Ecuador, also prioritized health and well-being through the release of the New Urban Agenda. Finally, the 2030 Sustainable Development Goals (SDGs) include a number of broad objectives that can only be met by addressing features of urbanization, such as poverty (SDG1), human health (SDG3), gender inequities (SDG5), water and sanitation (SDG6), decent work and economic growth (SDG8), reducing inequalities (SDG10) and climate action (SDG13). At least one goal, SDG 11, is dedicated to making cities inclusive, safe, sustainable, and resilient.

This chapter briefly reviews the historical debates around the connections between human health and urbanization and highlights some challenges for addressing twenty-first century urbanization. Twenty-first century urbanization presents new challenges for urban health (Galea et al. 2005). First, much rapid urbanization is happening in medium to small-size cities, not the mega-city growth the planet experienced through much of the twentieth century. These cities may not have the institutional structures or

national government support to plan for rapid growth and related health needs. Second, twenty-first century urbanization, particularly in sub-Saharan Africa, is not always accompanied by economic development, as was frequently the case in the nineteenth and twentieth centuries. Informal work and living conditions characterize much of planetary urbanization in the twenty-first century, and this can contribute to large portions of society being 'unseen' and 'unrecognized' by governments and international organizations interested in global sustainability and poverty alleviation. Third, and related to the second challenge, is that twenty-first century urbanization is characterized by rising and persistent social inequalities—poverty, discrimination, and spatial marginalization of minority ethnic groups, religions, migrants, refugees, and others. Cities in the twenty-first century are more diverse than their nineteenth century counterparts in terms of their populations, social characteristics, governance structures, and built environments. Further, the health outcomes that afflict urban dwellers are different than those of 150–100 years ago. New and drug resistant infectious diseases are combined with non-communicable diseases and issues of mental health and ageing in twenty-first century cities. Thus, we need new frameworks for understanding and addressing twenty-first century urban health.

This chapter explores how urbanization has and will continue to act as a fundamental determinant of human health (Galea et al. 2005). As I will show next, concerns with the well-being of urban populations has shaped global public from nineteenth century theories of miasma, to twentieth-century germ theory, to today's biomedical model, which attributes disease to unhealthy lifestyles, behaviours, and/or genetics (Porter 1999). For example, in the nineteenth century the urban Sanitary Era built water and sewer systems, required housing to have ventilation and cleaned streets. By the twentieth century, cities were chlorinating drinking water and pasteurizing milk to protect populations from disease and later, education and restrictions on 'unhealthy behaviours' such as tobacco use, shaped urban health. By the end of the twentieth century, epidemiologists began to re-emphasize that the social determinants of health (SDOH), or the institutional and structural forces including living condition, the distribution of wealth and power are the key drivers of population health. I will suggest that an emerging framework of population health that builds on the SDOH called 'toxic stress' reflects a twenty-first century evolution in urban health understanding and

action. *Toxic or chronic stress*, which I explain in more detail to follow, occurs when a group experiences adverse insults over a lifetime, often from in-utero through old age. These insults or 'stressors' have multiple sources and are often a combination of negative social—such as racism and segregation—economic, and physical exposures. These insults cause our body's immune system to 'over-react' through constant release of fight-or-flight hormones such as adrenaline and cortisol, and this wears away at our immune response, weakening our biologic response to infections and damaging our brain, heart, lungs, and other vital organs (McEwen and McEwen 2017). I will suggest here that twenty-first century urban health must take seriously the toxic stress hypothesis and this represent the *fourth wave* for urban health, with sanitation, germs, and genetics being the first three major public health movements.

Today, most urban health interventions are not focused on reducing multiple stressors in communities but rather on bringing either social services, primary care, economic opportunities, or physical improvements to urban residents or their neighbourhoods. Interventions tend to focus either on people or places, but rarely both at the same time. Interventions are generally conceptualized and led by experts, and focused on one disease, one risk factor, one hazardous exposure, one population group, or one suspected 'cause' of poor urban health, such as poverty (Corburn 2005). More care, more places offering care, more prevention, and more services tend to be the focus of many urban health strategies. This is what I call the *health in cities approach*, which focuses on healthy people but rarely on improving places, living conditions, or changing the institutions and policies that shape health opportunities or the presence of adverse stressors. In this chapter, I discuss twenty-first century urbanization and health by first reviewing some urban health history. I then highlight how twenty-first century cities, the physical, social, and political conditions, are linked to human health. I then explore the toxic stress framework and reveal its implications for twenty-first century framing of urban health. I close with some ideas for more healthy urban governance that embraces complexity science, uses processes of ecological adaptive management, and emphasizes the expertise of city residents as key participants and beneficiaries of urban health problem solving.

Modern urbanization and human health: a brief history

The notion that our urban environment—or the places where we live and work—influences human health is not new. Hippocrates, for some the Western father of medicine, noted in his *Airs, Waters, Places* (370 BC) that '[y]ou will find, as a general rule, that the constitutions and habits of a people follow the nature of the land where they live'. By the 1820s, French epidemiologist Louis René Villermé highlighted that the wealthier the Parisian neighbourhood, or Arrondissement, the lower the mortality rate and likelihood of illness. Edwin Chadwick's 'Report on the Sanitary Conditions of the Labouring Population in Great Britain in 1842', documented unsanitary living conditions afflicting the urban poor across Britain and contributed to the Royal Commission on the Health of Towns concluding that physical changes to the city were necessary to improve the well-being of the poor (Chadwick 1842, p. 87). Miasma—filth or dirty air—was the leading theory of disease causation, and sanitary commissions were created in European and American cities to clean up urban environments with the hope of arresting infectious disease epidemics (Duffy 1990). Sanitary engineers tended to address urban health issues by employing new technologies to remove waste by, for instance, piping it away from cities into rivers and oceans (Peterson 1979). Engineers laid claim to having the knowledge for designing healthy water delivery, street networks, and sewer systems—the 'arteries of the city'. When removing the miasma did not seem to reduce disease, the sick were removed from society. *Contagion*, the belief in the direct passage of poison from one person to another, led to large quarantines of immigrants and justified state-sponsored interventions in the economy (Porter 1999).

Early twentieth century urbanization and health: germ theory

By the turn of the new century, it was well-known in public health that both miasma and contagion failed to explain certain aspects of urban health, such as why, with ubiquitous filth, epidemics only occurred sometimes and in some places. By this time, the driving ideology in public health shifted to *germ theory*, which stated that microbes were the specific agents that caused infectious disease (Susser and Stein 2009). Medical treatment and disease management began to replace strategies of physically removing harms, and public health shifted toward laboratory research and interventions aimed at eliminating bacteria, such as vaccinations, pasteurization of milk, and

chlorination of municipal drinking water supplies (Leavitt 1982). Separate municipal bureaucracies emerged during this era to manage these urban improvement schemes, such as water service delivery infrastructure, sewage systems, public housing, parks and recreation, school-based health, and others, resulting in greater fragmentation and segmentation of work in urban health (Peterson 1979).

The model of laboratory science seen as producing definitive, apolitical knowledge also contributed to a view of city management during this time. City planners interested in improving health were often confronted with finding ways to pay for politically and economically controversial infrastructure projects that often wouldn't produce results for a decade or more (Rosen 1993). Planners and engineers turned to the prestige of laboratory science for a model of city management, since in the lab results were often unquestioned since researchers were viewed as neutral and detached from the social context where investigations were taking place, inputs into lab experiments were highly controlled and restricted, and analytic techniques were mechanical and standardized, so that results from a lab anywhere could be applied everywhere. City managers demanded political autonomy in the interest of the city's health, and used new 'efficiency' technologies such as benefit-cost analyses, land use zoning, and long-range comprehensive planning, to radically alter urban governance (Corburn 2013, 2017).

Social inequalities kept the fields of science, medicine, and urban management somewhat linked. In 1906, W.E.B. Du Bois published *The Health and Physique of the Negro American* and used data from census reports, vital statistics, and insurance company records to generate some of the first documentation of the poor health status of African Americans living in both southern and northern cities in comparison to white Americans. Du Bois questioned whether improvements in science, technology, housing, and other services were benefiting all Americans and concluded that racial health disparities were a result of social conditions—not Eugenic ideas of inherent racial inferiority that were commonly accepted in science and medicine at the time (Du Bois 1906).

Importantly, social movements organized to shape the priorities and direction of urban health. Unequal distributions of power in cities contributed to women reformers, such as Alice Hamilton, Florence Kelley, and Jane Addams, to organize workers and immigrants in the United States

to demand safer workplaces, social housing, and urban green spaces for play (Porter 1999). Importantly, urban public health was not just about science but shaped by power and politics of civil society and social movements (Szreter 2005).

Colonialism, urbanization, and health

Today's cities, and many of the challenges they face, can't be divorced from colonial-era strategies that blamed indigenous populations for disease and subsequently segregated them from life-supporting resources. Almost all migrants to colonial cities had to make or find their own housing. Laws of private property were almost non-existent for indigenous peoples in colonialized Asia, Africa, and the Caribbean in the nineteenth century. Doctors became all-purpose experts and authorities frequently put in charge of everything from 'native affairs' to town or city planning (Home 2013). Colonial medical authorities tended to blame the racial characteristics, living conditions and practices of the indigenous populations for diseases, and to make indigenous populations research subjects to help colonial powers control infectious diseases. Eugenics was the pseudo-science arguing that indigenous and slave populations were susceptible to disease due to their inherent racial inferiority (Curtain 1985). Francis Galton coined the term eugenics and the movement argued that the 'feeble minded' and destitute segments of urban society suffered from inherited genetic defects. One solution of eugenic societies that emerged in cities around the world was to control reproduction through forced sterilization. The advocates behind eugenics aimed to challenge the sanitarian ideas that reducing poverty, improving environmental and housing conditions would actually improve the health of the poor and were worth the expense (Krieger 2011). British sanitary engineers were sent to such colonial cities as Singapore, Calcutta, Pune, Lagos, and Cape Town, to help control infectious disease outbreaks. In practice, urban sanitarians used eugenic ideas of racial inferiority to justify subjecting indigenous practices to inspection, regulation, and disciplinary action—including razing homes and markets to 'ventilate' slums of their 'unhealthy' dark and dirty conditions (Garside 1988).

The biomedical model, housing and the fractured city: 1950s–1990s

By the mid-century, the driving theory in public health would shift again to the *biomedical model* of disease (Susser and Stein 2009). This model combined laboratory science with a focus on individuals and attributed morbidity and mortality to molecular-level pathogens brought about by lifestyles, behaviours, hereditary biology, or genetics. The biomedical model would provide public health with explanations for emerging chronic diseases such as heart disease, and shifted research and interventions to personal health 'risk factors' such as smoking, diet, and exercise (Krieger 2011). By the 1940s, the United States Housing Authority and New York City's Public Health Department blamed slums for crime and infant mortality and was advocating for removing slums and replacing them with modern, high-rise buildings (Corburn 2013; Hachmann et al. 2018). The American Public Health Association published a guide called 'Planning the Neighborhood' in 1948 that also recommended removing older slums in cities and suggested healthy housing was new, suburban-style development (APHA 1948). Slums and slum dwellers became synonymous with unhealthy places and populations. As Gilbert notes:

> The most worrying ingredient in most people's use of the word 'slum,' therefore, is the survival of these wholly negative connotations. Slum dwellers are not just people living in poor housing; they are considered by others to be people with personal defects. In Brazil, a favelado is not just someone who lives in a favela, he or she is thought to be someone who deserves to live there. (Gilbert 2007)

Slums often generated fear in the minds and actions of those who do not live there and the institutional response was largely to eliminate, not improve, slums. Slum had effectively become a pejorative and associated with unhealthiness, no matter the context or time period (Rao 2006).

For instance, American housing policies from this time through the 1950s subsidized new single-family suburban homes by offering mortgage insurance for new homes but not to older homes located within cities and urban ghettos (Corburn 2009). The US housing policies also mandated suburban design patterns that would set the stage for twentieth-century suburban sprawl. The US Housing Act of 1949 institutionalized urban renewal, where municipalities began razing 'slum' neighbourhoods and

displacing thousands of poor, largely African-American residents. Urban renewal was a programme and theory that aimed to remove downtown blight—still viewed as the cause of moral evil and the breeding ground for disease—and rebuild whole sections of the city using the best of modern technology and scientifically rational design. Yet urban renewal tended to only increase poverty for residents of poor neighbourhoods because their homes were replaced with either inadequate public housing or, as was more often the case, private real estate developers acquired the downtown land cheaply and opted not to build new housing but expensive high-rise office towers (Fullilove 2004). Not only were neighbourhoods physically fractured, but social and emotional ties, trust, and notions of collective efficacy were also severed by urban renewal, further diminishing the health-promoting resources available for African Americans. Shut out from most new suburbs, African Americans were denied other health benefits that can come with homeownership, such as capital accumulation, access to better-funded schools, and participation in the growing economy (Fullilove 2004).

Twenty-first century urban health equity

By the mid-1980s, academics, government agencies, and the World Health Organization (WHO) came together to create the Healthy Cities programme in order to re-invigorate the linkages between city planning and public health (Duhl and Sanchez 1999). Focused primarily in Europe, the Healthy Cities programme enrolled cities to draft 'healthy city plans' and share examples of the opportunities and barriers for planning more Healthy Cities. By the 1990s, public health researchers began to re-conceptualize explanations for the distribution of disease across populations in order to explain health disparities, energizing the field of social epidemiology (Krieger 2011). Urban place inequities—such as residential segregation, urban divestment, and environmental injustices—began to be seen by epidemiologists by the early twenty-first century as linked SDOH (Kjellstrom et al. 2007).

How urbanization influences human health

The physical and built environments

The physical environments of cities still matter for health, such as whether there is access to safe and affordable drinking water, sanitation, drainage, and garbage collection. Urban air and noise pollution remain critical health determinants in highly industrialized cities of Europe and Latin America, as well as developing cities in China and sub-Saharan Africa (Lilford et al. 2017). Urban air pollution is linked to up to 1 million premature deaths and 1 million pre-native deaths each year. Over 90% of air pollution in cities in these countries is attributed to vehicle emissions brought about by high number of older vehicles coupled with poor vehicle maintenance, inadequate infrastructure and low fuel quality (Friel et al. 2011). Urban particulate matter is associated with cardiovascular death and asthma. Noise pollution, a common urban nuisance, is associated with hearing impairment, hypertension, and ischaemic heart disease. Exposure to environmental pathogens in urban air and water can contribute to both infectious (i.e. parasitic diseases, diarrheal diseases, intestinal parasites, etc.) and non-infectious diseases.

Pedestrian conflicts with motor vehicles are one of the leading causes of injuries in urban areas. When a new development project includes new housing and commercial activity, pedestrian activity increases, and this can lead to an increase in injuries. However, greater pedestrian activity can promote physical activity that reduces heart disease, stroke, and mental illness, and increase functional status and the longevity of independence among the elderly. Creating new opportunities for pedestrian activity can also improve well-being by increasing the likelihood of social interactions that can reduce feelings of isolation. However, the construction of highways contributes to vehicular air pollution and suburban sprawl, while the lack of or inadequate transport inhibits access to employment and health-promoting services, especially for the urban poor. Highways and streets can limit green open space, which can act as a site for physical activity, social interactions, and an urban heat sink, reducing the likelihood of adverse human health impacts from climate change induced urban heat islands (Frumkin 2003).

The social environment and urban health

The physical and social environments of cities frequently interact and cannot be disassociated when trying to understand and improve urban health inequities. The urban social environment includes the institutions that shape

the structure and characteristics of relationships and opportunities among people and different population groups within a given community (Kjellstrom et al. 2007). Perhaps the most well researched aspect of the social environment that influences health is economic status or class. While debate continues whether absolute or relative poverty matter more for influencing health, there is agreement that being poor in any city increases one likelihood of a range of health risks across the life-course, from infant mortality and low birth weight, to stunted physical and cognitive development to early on-set chronic illnesses and higher rates of infections (Grant et al. 2017).

The economic 'environment' also influences well-being. Neighbourhoods with high concentrations of liquor stores also have high rates of addiction. However, local businesses can act as a source for employment and culturally-appropriate food and other services. Displacement of local businesses can adversely impact health by altering the availability and affordability of essential goods and services and the type of local employment possibilities. Business displacement can also contribute to physical blight—the tooth-gaped landscape all too common in poor neighbourhoods where widespread property abandonment has taken hold. Property abandonment can adversely influence health by increasing the likelihood of illegal dumping of garbage and hazardous wastes (Ellaway et al. 2012).

The social environment also influences health through a variety of other pathways, including the support of individual or group behaviours that affect health, buffering or enhancing the impact of stressors, and providing access to goods and services that influence health (for example, housing, food, informal healthcare) (Krieger 2011). Limited social supports may predispose persons to poorer coping and adverse health. High levels of social stressors such as social isolation and violence, are also known to adversely impact the health of urban residents. In cities, the greater spatial proximity of one's social networks may accentuate their role in shaping individual and population health (Friel et al. 2011).

Perhaps the most crucial social and political force in cities that influences health is spatial segregation. Many cities worldwide are highly segregated with discrimination against certain racial, ethnic, caste or tribal groups often acting as justification (Galea et al. 2005). Spatial segregation can have multiple effects, including the enforcement of homogeneity in resources and

social network ties and suppressing diversity that may benefit persons of lower socioeconomic status. Persons who live in segregated communities may have disproportionate exposure, susceptibility, and response to economic and social deprivation, toxic substances, and hazardous conditions (Corburn 2009).

Table 7.6.1 Urbanization and human health: resources and risks

Health resource	Urban physical and social influences on health (examples)
Environmental quality, including noise, air, soil, and water pollution	Vehicle emissions exacerbate respiratory disease and increase cardiopulmonary mortality, while indoor allergens exacerbate asthma Chronic noise exposure adversely harms sleep, temperament, hearing, and blood pressure, all of which can lead to developmental delays in children Trees and green space remove air pollution from the air and mitigate the urban heat island effect
Climate change resiliency, including protection from heat, draught, flooding, food supply disruptions, and other events	Heat islands, or elevated temperatures, are more frequent in dense, urban areas with limited green spaces Extreme weather events, such as draught and typhoons, exacerbate vulnerability of the urban poor already living on precarious land Climate change is contributing to an increase prevalence of vector-borne diseases in urban areas, such as dengue, malaria, and zika
Access to high-quality transit and safe roadways, sidewalks, and bicycle lanes	Vehicle/pedestrian injuries are most severe where sidewalks and crosswalks are non-existent Sidewalks and bicycle lanes facilitate physical activity, reducing heart disease, diabetes, obesity, blood pressure, osteoporosis, and symptoms of depression Public transit provides access to employment, education, parks, and healthcare services
Access to quality childcare, education, and healthcare facilities	Quality childcare can build disease immunities and increase likelihood of future educational attainment and earnings Education can enhance health literacy about preventative behaviours and services Timely access to primary health services prevents serious illness
Affordable, safe, stable, and socially integrated housing	Crowded and substandard housing conditions increase risks for infections, respiratory disease, fires, and stress Unaffordable rents or mortgages result in trade-offs between housing, food, and medical care Racial residential segregation limits economic and educational opportunities, concentrates disadvantage and increases social distance between racial/ethnic groups
Access to safe and quality open space, parks, cultural and recreational facilities	Clean and safe parks can increase the frequency of physical activity Cultural activities can promote cross-cultural understanding, decrease violence, and enhance social cohesion

Health resource	Urban physical and social influences on health (examples)
Employment providing meaningful, safe, and living wage jobs	Higher income is associated with better overall health, reduced mortality, and higher emotional stability Unemployment is a source of chronic stress, while job autonomy increases self-esteem
Access to affordable and quality goods and services	Neighbourhood grocery stores support nutritious diets Local financial institutions help families create and maintain wealth
Protection from crime and physical violence	Indirect effects of violence and crime include fear, stress, anxiety, and unhealthy coping behaviours, overeating, smoking, and alcohol/drug abuse Fear of crime can force children to stay indoors, increasingly exposure to toxic indoor air and allergens, and limiting physical activity outside
Social cohesion and political power	Physical and emotional support buffers stressful situations, prevents isolation, contributes to self-esteem, and reduces the risk of early death Stress from severed/lack of social ties/support can contribute to low birth weight, which increases risk of infant death, slow cognitive development, hyperactivity, breathing problems, overweight, and heart disease

Urbanization, governance, and health

The physical and social characteristics and dynamics in cities that influence health do not happen randomly or by accident. Cities and metropolitan regions more generally are not shaped by faceless forces of natural succession and competition. People and organized groups or coalitions actively accomplish cities and urban neighbourhoods, and the process is rarely the same from here to there. There are real winners and losers in the *political struggles* of place making, and static definitions of physical and social variables rarely captures this dynamic of places. The political processes of urban place-making and remaking are what I refer to as ‘urban governance’. (Burris et al. 2007) As Szreter (2005) notes (see Chapter 1.2), social movements were critical in reshaping public health priorities, whose knowledge is considered, and how civil society plays an important role in democratic decision-making.

The term governance is broadly understood as attentive to the relationships between the overlapping spheres of political, economic, and social life, as each aim to influence collective action. Governance is not government, but is inherently about the struggle and conflict between formal institutions and organizations and informal norms and practices. Urban governance includes a complex mix of different contexts, actors, arenas, and issues, where struggles over power can be manifested in public discourses or tacit day-to-day routines. An urban governance approach to urban health is attentive to both processes and outcomes, and must ask questions such as: what conditions lead to planners using or abusing power, responding to or even resisting market forces, working to empower some groups and dis-empower others, promoting multiparty consensual decision-making discourses or simply rationalizing decisions already made? (Corburn 2013). The governance approach views urban planning as a process that includes the shaping of public agendas and attention, available evidence, and norms of inquiry, inclusive or exclusive deliberations, and responses (or lack thereof) to bias, discrimination, inequality, and a recalcitrant state. An attention to governance moves health equity planning away from only focusing on vulnerable people or places to also include altering the political processes and institutions that work to maintain the social inequities driving urban health inequities (Friel et al. 2011).

Toward a twenty-first century science for urbanization and health: addressing toxic stress

Twenty first century urbanization must embrace the now well-documented idea that social stress can be toxic to the human body, especially when place-based stressors are chronic and cumulative across one's lifetime (McEwen and McEwen 2017). While stress can be life saving for most—think of the fight-or-flight mechanism—constant adversity is toxic, meaning that the prolonged activation of the stress response systems can disrupt the development of the brain architecture and other biologic systems. Some of the multiple, chronic stressors experienced by the poor and marginalized populations in cities appear in Figure 7.6.1 (Hajat et al. 2015). These stressors often begin in-utero, and individual behaviour changes alone cannot redress their impacts.

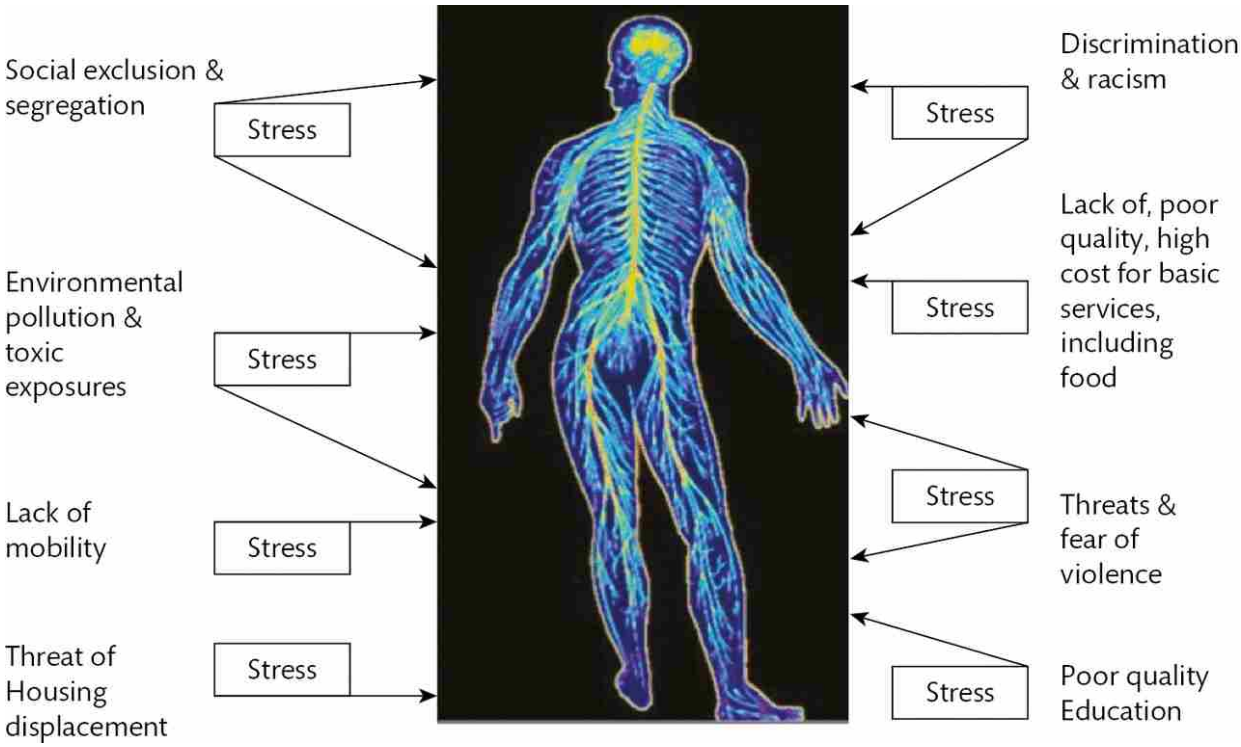

Fig. 7.6.1 Urban toxic stressors that adversely impact human health.
Corburn, J. 2013. Healthy City Planning: From Neighbourhood to National Health Equity. London: Routledge.

As shown in Figure 7.6.2, under ‘normal’ stressful situations the human body undergoes a range of physical and chemical responses, but primarily the hormones epinephrine (adrenaline) and cortisol are released to heighten one’s awareness, but these eventually ‘shut off’ when the threat is over and the body returns to homeostasis (Fig. 7.6.2, solid line). The body’s ability to maintain stability under stress has been called allostasis (McEwen and McEwen 2017). In toxic stress situations, stressors are constant and the ‘allostatic load’ continues to increase and the release of ‘fight-or-flight’ hormones does not properly regulate or shut-off (Fig. 7.6.2, dashed line). Increased allostatic load wears away at the immune system as it overworks to manage the hormonal releases and attempt to return to homeostasis. Under toxic stress circumstances, the oversecretion of cortisol and adrenaline trigger other biologic responses like poor immune response, poor glucose regulation, and constant feelings of hunger that can contribute to chronic diseases such as overweight and obesity, diabetes, hypertension,

cardiovascular disease, stroke, asthma, and mental health disorders (Velasquez-Manoff 2012). Some known toxic stressors include chronic poverty, racial, gender, and other forms of discrimination and marginalization, physical or emotional abuse, exposure to violence and housing instability (Berger and Sarnyai 2014). Allostaic load has been linked with changes in the length of telomeres, which are DNA-protein complexes capping the ends of chromosomes that protect them against damage. Telomere shortening is considered a marker of cellular ageing (Price et al. 2013).

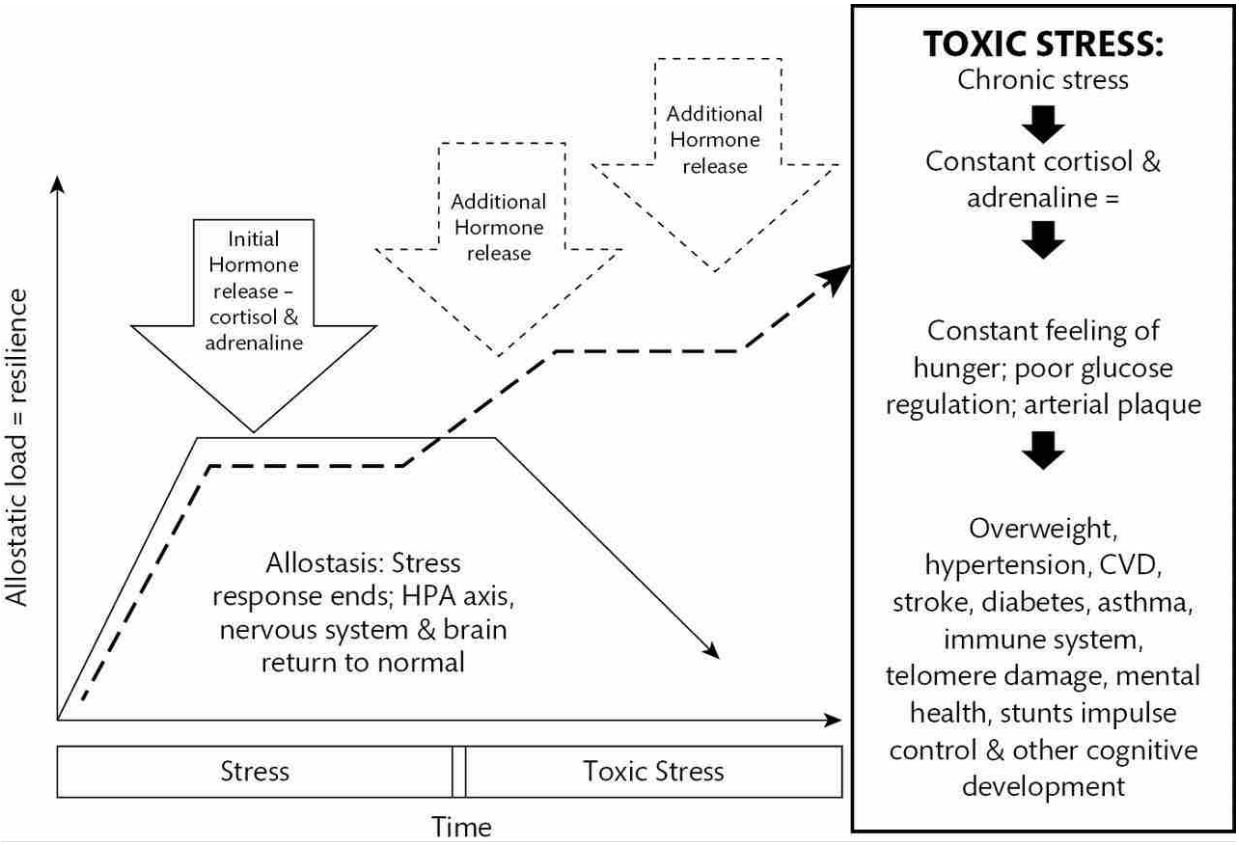

Fig. 7.6.2 Chronic stress and its biologic impacts.

Since populations in many deprived and impoverished areas of cities are likely experiencing multiple 'toxic stressors', twenty-first century urbanization and health must be attentive to the physical and social stressors in places, such as chronic poverty and discrimination, housing instability, and exposure to violence. The toxic stress idea suggests that a twenty-first

century science for the healthy city can no longer view a person as, for example, one day an African immigrant, another day born low birth weight, another day raised in a home bearing remnants of lead paint, another day subjected to racial discrimination at work, and still another day living in a racially segregated neighbourhood without a supermarket or access to transport. Just as the body does not neatly partition these experiences—all of which may serve to increase risk of uncontrolled hypertension and related morbidity and premature mortality—the twenty-first century urban health planner can no longer separate these spheres and sectors in research or practice (Corburn 2013).

Twenty-first century urbanization and health governance

Measuring and addressing urban toxic stress will demand new, interdisciplinary action-research into the context-specific factors that might be making particular urban residents unhealthy and more susceptible to disease, disability, and death. This work must privilege partnerships, participation, and power-sharing between scientists, the urban poor themselves, social movements, and state-level decision-makers. There is no one-size-fits all approach. I borrow a term from the Science Studies, economics, and development literatures to call this collaborative urban health approach *co-production* (Jasanoff 2004). In the co-production of urban health, science is understood as dependent on the natural world, as well as historical events, social practices, material resources, and institutions that contribute to the construction, dissemination, and use of scientific knowledge. Political decision-making, in the co-production framework, does not take ‘scientific knowledge’ as a given, but seeks to reveal how science is conducted, communicated, and used. The co-production model problematizes knowledge and notions of expertise, challenging hard distinctions between expert-lay ways of knowing. Acting to understand and improve urban health, under the co-production approach, requires a negotiation among the always partial and plural positions of professionals and lay people. The co-production model also destabilizes the dominant view in science policy-making that science can be uncritically accepted as ‘fact’ and ‘truth’. The destabilizing stories and emphasis on the need for ‘negotiating expertise’, suggest that a deliberative science is necessary for the co-production of slum health knowledge for action (Corburn 2005).

Adaptive ecosystem management offers a model of co-producing scientific research and practice for global urban health. Adaptive management acknowledges the failures of linear processes where narrow disciplinary scientists have aimed to develop complex models, predict long-term outcomes, and suggest one-time policy standards. Instead, adaptive management begins with an acknowledgement of the inherent complexity and uncertainty within systems, that this complexity demands an iterative, ongoing learning process among a range of expert stakeholders, and policy interventions must be adjusted to reflect newly acquired knowledge (Corburn 2013). Another difference between adaptive management and conventional science policy is that adaptive management does not postpone actions until definitive causality is known about a system, but rather emphasizes the importance of action in the face of uncertain science and couples these decisions tightly to rigorous monitoring.

Urban climate change adaptation

Perhaps the key twenty-first century urban health challenge is ensuring the poor and most vulnerable residents and communities are able to adapt to a changing climate. The urban poor are some of the most vulnerable to the human health impacts of global climate change since, for instance, low-income, urban neighbourhoods may have less green space, housing located on flood-prone land, and fewer economic and social resources to escape and recover from heat, weather, and other climate-related stressors. Urban climate justice demands co-produced climate change adaptation plans that reduce risk and improve the health status of the poor and already vulnerable communities. This will demand new investments in urban infrastructure, such as housing, water, and sanitation, social and healthcare services, in urban communities that already experience health inequities. As many local governments, particularly in the Global South, experience severe capacity and resource constraints, co-produced adaptation demands a leadership role for the urban poor and civil society actors. Using this approach, urban climate justice would aim to not just reduce existing risks but also build-upon local institutional strengths and civic capacities.

One such approach, used in Quito, Ecuador, resulted in the city's Climate Change Action Plan that articulated the needs of marginalized groups, facilitated a youth-led Convention on Climate Change, incorporated local

traditional and indigenous knowledge in the process, and defined ongoing civil society participation for climate action. Based on recommendations from Quito's plan, the municipality has invested in socially vulnerable groups by building new water and sewerage infrastructure, social housing that enabled the poor to avoid living in unsafe structures on steep hillsides, reforested areas of the municipality as an 'ecosystem service' that could reduce mudslides and cool temperatures, and community-and school-based organic farming (AGRUPAR, Agricultura Urbana Participativa) that improves nutrition and food security for the urban poor (Chu et al. 2016). Quito's food programme has multiple co-benefits; reducing malnutrition and vulnerability to climate-induced food supply disruptions for the urban poor, increasing employment and incomes, improving learning for children, enhancing water conservation and reuse, and reducing carbon emissions by limiting the travel distance along the food supply chain.

Health in all urban policies

Health in All Policies (HiAP) is an approach to decision-making that aims to put the adaptive and co-production approach into practice (Shankardass et al. 2018). HiAP recognizes most public policies have the potential to influence health and health equity, either positively or negatively, but policymakers outside of the health sector may not be routinely considering the health consequences of their choices and thereby missing opportunities to advance health. HiAP emerged, in part, from the WHO's Declaration of Alma-Ata in 1978 and reflects numerous international calls for policy action to address the SDOH (Freiler et al. 2013). The European Union endorsed HiAP in 2006 and the governments of Finland, Norway, Sweden, United Kingdom, Canada, South Australia, Malaysia, Sri Lanka, Iran, and Brazil have all adopted some form of HiAP within governmental practice. The Dutch government actively supports municipalities to draft and implement HiAP strategies, but very few have managed to complete and implement these strategies, noting the difficulty in getting government actors and institutions outside the health sector to consider health impacts in their work (Storm et al. 2014). Some cities are actively working to integrate HiAP into their land use and planning decision-making. For example, Washington, DC passed the Sustainable DC Transformation Order in 2013, creating a HiAP Task Force

and the Chicago Department of Public Health created the Healthy Chicago Interagency Council to integrate health across all city departments.

The City of Richmond, California, in the San Francisco Bay Area, became the first city in the US to pass a HiAP ordinance in 2014 (Corburn et al. 2014). Richmond's HiAP Ordinance is aligned with their General Plan and Budget, and includes intervention areas focused on how city policy, management, and service decisions can reduce the multiple toxic stressors residents and planners identified in Richmond. The HiAP Ordinance address six planning areas, including: (1) Governance and Leadership; (2) Economic Development and Education; (3) Full Service and Safe Communities; (4) Neighbourhood Built Environments; (5) Environmental Health and Justice; and (6) Quality and Accessible Health Homes and Social Services. In addition, HiAP includes a racial equity evaluation for all city projects, policies, and plans (Corburn et al. 2014).

Conclusions: pursuing greater urban health equity in the twenty-first century

Contemporary inquiry into global urbanization and health can learn from the past to better understand how current trends gained resonance and what alternative futures might be possible. Alternative paradigms can be both practical and socially just, as the examples here suggest. However, more work needs to be done to avoid overgeneralizations and investigate specific contexts, how culture and politics shapes urbanization and appropriate health interventions. As global efforts to prioritize urban health continue, such as through the SDGs, a historical perspective is necessary to critically re-engage with urbanization as a structural determinant of health (WHO and UN Habitat 2016).

As suggested here, re-orienting urbanization and the institutions behind it toward health will require moving toward integrated, multisector partnerships that target equity. Urban planners have a specific role to play by explicitly expanding the narrow framing of the 'built environment and health' to include social and political determinants of health, such as an attention to how racial discrimination contributes to place-based toxic stressors. This also demands that planners work with epidemiologists and others to break-down issue and sector fragmentation and the tendency in

medicine and public health to focus only on one disease, risk factor, or behavioural change at a time. Civil society involvement, such as through activist social movements and 'citizen scientists', is crucial to ensure twenty-first century urbanization serves the well-being of the most vulnerable and marginalized populations and places.

As discussed here, those concerned with urban health cannot wait until the science of health equity is definitive, but instead can rely on over a century of evidence that simultaneously addressing social, environmental, and economic inequalities can promote greater urban health equity.

Epidemiology and prevention of cardiovascular disease

Nathan D. Wong and Wenjun Fan

Introduction

Cardiovascular diseases (CVDs) comprise the leading cause of morbidity and mortality, with recent 2015 estimates noting 422.7 million cases and 17.9 million deaths (Roth et al. 2017) and expected to grow to 23.6 million by the year 2030; 80% of these deaths occur in lower and middle income countries (WHO 2011). It is the largest contributor to non-communicable diseases (NCDs) that are now responsible for the largest share of morbidity and mortality worldwide. The incidence of CVD, including coronary heart disease, peripheral arterial disease, heart failure, and stroke, as well as the prevalence of key risk factors, varies greatly according to geographical region, gender, and ethnic background. Multiple longitudinal epidemiological studies have provided valuable insights into the natural history and risk factors associated with the development and prognosis of CVD. Randomized clinical trials have demonstrated the value of management of several key risk factors for both the primary and secondary prevention of CVD. This chapter discusses the epidemiology of CVD, its associated risk factors and evidence for their control, assessment of CVD risk, and the evidence behind the control of CVD risk factors for the prevention of CVD.

Definitions, incidence, and distribution

Cardiovascular disease comprises many conditions, including coronary heart disease, heart failure, rheumatic fever/rheumatic heart disease, stroke, and congenital heart disease. Ischaemic heart disease is typically the

predominant manifestation of CVD and responsible for 46% of deaths due to CVD in men and 38% in women, followed closely by cerebrovascular disease at 34% and 37%, respectively (WHO 2011). Certain regions of the world, however, show ischaemic heart disease to be the cause of cardiovascular deaths in more than 50% of persons, with significant regional variations (Roth et al. 2017) (Fig. 8.1.1). While the burden of CVD was highest in Western countries during much of the 20th century, the highest mortality rates of CVD now occur among certain central Asian and Middle Eastern regions (Roth et al. 2017) (Fig. 8.1.2). By country, total death rates (per 100,000) from CVD, CHD, and stroke for the years 2012–2015 are highest in the Russian Federation for both men (1,041, 709, and 204, respectively) and women (433, 286, and 106, respectively) and among the lowest in Israel for men (96, 45, and 20, respectively) and in France for women (40, 9, and 12, respectively), with intermediate rates in the US (234, 124, and 27, respectively, in men and 117, 48, and 20, respectively, in women) (Benjamin et al. 2018).

In the United States, the overall prevalence of CVD in the years 2011–2014 (including hypertension) increases dramatically from 13.5% in men between the ages 20 and 39 years to 84.4% for men above 80+ years old; the corresponding figures for women were 11.5% and 86.5% (Benjamin et al. 2018).

Of note, however, is the substantial reduction in CVD mortality rates in the US over the past three decades, both in men and in women, although absolute mortality from CVD in women, since 1985 has exceed that observed in men, until recent years when the number of deaths has been fewer in women than in men. These declines have been attributed both to improved treatments for CVD and its associated risk factors and to improvements in lifestyle factors such as substantial declines in cigarette smoking, although the increasing obesity epidemic is expected to negate some of these reductions in CVD.

Myocardial infarction, angina pectoris, and sudden coronary death are the major clinical manifestations of CHD. CHD initially presents as sudden coronary death in approximately one-third of cases. Other forms of documented CHD include procedures done as a result of documented significant atherosclerosis, such as coronary artery bypass grafting (CABG) or percutaneous coronary interventions (PCIs), including angioplasty and stenting. Persons with documented significant disease from a coronary angiogram, echocardiogram, nuclear myocardial perfusion, magnetic resonance imaging, or computed tomography angiographic or coronary calcium scan can also designate the presence of CHD; however, because the definitions used to define significant CHD vary and these findings often do not result in hospitalization or hard CHD events, such persons are not normally counted as incident or prevalent CHD, particularly for the purposes of endpoints in epidemiologic studies or clinical trials. Non-fatal or fatal myocardial infarction or sudden coronary death are most typically included as ‘hard’ CHD endpoints, while ‘total’ CHD may additionally include angina requiring hospitalization a well as PCI or CABG.

CHD prevalence rates vary dramatically by age and gender in the United States. The most recent statistics from 2011 to 2014 showed that 16.5 million US adults aged 20 years and older have CHD; this varies widely by race and gender within the United States. For example, for males, while the overall prevalence was 7.4%, the prevalence in non-Hispanic white males was 7.7%, in black males 7.1%, in Mexican-American males 5.9%, and in Asian males 5.0%. The corresponding figures for females were 5.3% overall, 5.3% in non-Hispanic white females, 5.7% in black females, 6.1% in Mexican-American females and 2.6% in Asian females. An American experiences a heart attack every 40 seconds. CHD makes up more than half of all CVD deaths in men and women <75 years of age, with a lifetime risk (≥2 major risk factors) of developing CHD after age 55 years, of 37.5% for men and 18.3% for women (Benjamin et al. 2018).

Other important manifestations of CVD include cerebrovascular disease (including stroke and transient ischaemic attacks), heart failure, atrial fibrillation, and peripheral arterial disease, in particular. Somewhat less common but still of significance are valvular heart disease, rheumatic heart disease, and bacterial and valvular endocarditis.

Cerebrovascular disease includes stroke and transient ischaemic attacks (TIA). Stroke prevalence in the United States ranges from <1% in those <40

years of age to 14% in both genders in those aged 80 years and over. An estimated 7.2 million Americans aged 20 years and over have had a stroke; each year an estimated 795,000 persons experience a new or recurrent stroke, with approximately 610,000 of these cases being first attacks. Of all strokes, about 87% are ischaemic and 10% are intracerebral haemorrhagic strokes, and 3% subarachnoid haemorrhage strokes (Benjamin et al. 2018). The self-reported prevalence of physician-diagnosed TIAs is about 2.3%, translating to approximately 5 million persons, but the true prevalence is likely to be greater as many with neurological symptoms consistent of TIA fail to report them to their healthcare provider. About 12% of all strokes are preceded by a TIA.

While mortality rates due to total CVD, and especially CHD and stroke, have declined substantially over the past 30 years, hospitalizations due to total CVD have increased, much of this fuelled by the more than doubling in the number of hospitalizations due to heart failure between 1980 and 2010 (1,023,000 in 2010 in the United States). It is projected that this will increase by another 25% by the year 2030. The prevalence of heart failure ranges from <1% in those under age 40 to 14.1% of men and 13.4% of women aged 80 years and over.

Peripheral arterial disease is highly prevalent affecting approximately 8.5 million Americans aged 40 years and over and is associated with significant morbidity and mortality; it is most common in older persons over age 55 and is asymptomatic in most cases, being diagnosed by a Doppler tool measuring the ankle brachial index, where a value of <0.9 is diagnostic of peripheral arterial disease. The estimated prevalence in the US population is 7.2%; only about 10% of those with peripheral arterial disease actually have the classic symptoms of intermittent claudication (or leg pain) (Benjamin et al. 2018).

Estimates of the prevalence of valvular heart disease, which includes aortic, mitral, and tricuspid valve disorders range from 0.3% in those under the age of 45 years to 11.7% in those aged 75 years and over. Rheumatic heart disease while uncommon in developed countries, affects more than 15 million individuals in Africa, Asia, and the Pacific, causing over 200,000 deaths annually. Infective endocarditis is relatively rare and results from formation of non-bacterial thrombotic endocarditis on the surface of a cardiac valve, bacteraemia, and adherence of the bacteria in the bloodstream; the estimated risk in the general population is as low as 1 case per 14 million dental procedures (Benjamin et al. 2018).

Risk factors for cardiovascular disease

The Framingham Heart Study, the seminal epidemiologic study of CVD, is a large longitudinal investigation begun in 1948 in the small town of Framingham, Massachusetts, USA. The original cohort of 5,209 participants aged 30–62 years of age received biennial physical examinations, risk factor assessments, and surveillance for CVD events (Wong and Levy 2013). The Framingham study was instrumental in the original identification of many of the factors that are associated with an increased risk of CVD, and in 1961, coined for the first time, the term ‘risk factors’ that is widely utilized in many different fields of medicine today (Kannel et al. 1961). The increased awareness of major risk factors for CVD initially identified by the Framingham Heart Study and by other researchers provided the impetus for important public health initiatives against smoking in the 1960s, hypertension in the 1970s, and hypercholesterolemia in the 1980s. More recently, obesity and physical inactivity have also been recognized as key risk factors for CVD. Diabetes is also now widely regarded as a CHD risk equivalent and the importance of a clustering of major cardiometabolic risk factors, commonly referred to as the metabolic syndrome, has received significant attention from the research and clinical community (Grundy et al. 2005). Risk factors often cluster together, and the number of risk factors present and their co-occurrence and is directly related to the incidence of CHD (Fig. 8.1.3). Importantly, it was the Framingham Heart Study that first introduced the concept of multivariable or global risk assessment for coronary heart disease (see also section to follow on global risk assessment) (Wilson et al. 1998).

	A	B	C	D
Blood Pressure (mmHg)	120/80	140/90	140/90	140/90
Total Cholesterol (mg/dl)	200	240	240	240
HDL Cholesterol (mg/dl)	50	50	40	40
Diabetes	No	No	Yes	Yes
Cigarettes	No	No	No	Yes

Source: data from Wilson PWF et al. Prediction of Coronary Heart Disease Using Risk Factor Categories. *Circulation* 1998 97: 1837–47.

Family history and genomics. A family history of premature CHD is a well-established, but unmodifiable risk factor for future CHD, and can sometimes be the crucial and single most important risk factor in predisposing an individual to early CHD (Hopkins et al. 2000; Williams et al. 2001). A large proportion of heart attacks or strokes occurring at a young age are felt to be attributable to inherited or familial predisposition. Hence, knowledge of an individual's family history can help guide preventive efforts. A family history of premature CHD is generally defined as having a

male first-degree relative experiencing a first manifestation of CHD under the age of 45, or a female first-degree relative experiencing CHD under the age of 55. The number of affected relatives with premature CHD is also felt to be an important factor, since those with 1 affected relative can be shown to have a fourfold greater risk of CHD, while those with 2 or more affected relatives may have more than a 12-fold greater risk of CHD compared to those without any affected relatives (Hopkins et al. 2000). Moreover, it has been shown that 35% of all early CHD occurs in just 3.2% of families, all of whom have a strong positive family history of CHD. Familial hypercholesterolemia (FH) is an autosomal dominant condition associated with very high levels of total and LDL-cholesterol (total cholesterol levels exceeding 500 are commonly reported) where individuals inherit from one or both parents (homozygous) a defective LDL-cholesterol receptor gene. Affected individuals have been known to have heart attacks and die by age 20 and FH is among the most widely studied genetic conditions responsible for CHD. Other genetic defects responsible for hypertension, obesity, diabetes, and other major cardiovascular risk factors have also been identified and are the subject of major investigations (Williams et al. 2001).

In recent years, with the ability to sequence the entire human genome, key single nucleotide polymorphisms (SNPs) have been identified and linked to the likelihood of CHD, although with a much higher threshold required to confirm a statistically significant relationship ($p = 10^{-8}$) (Schunkert et al. 2011). One that has received significant attention is 9p21 because of its strong association with CHD (Palomaki et al. 2010). However, the utility of such SNPs in improving the ability to predict CHD over traditional risk factors is only modest and current guidelines have not recommended genomic screening due to the thus far limited demonstrated clinical utility.

Of great recent interest is the emerging role of Mendelian randomization studies to estimate the effect of lifetime exposure to a given risk factor (or absence of risk factor) on risk of CHD. For instance, in one meta-analysis of studies involving 312,321 participants, examining the effect of long-term exposure to lower LDL-cholesterol on the risk of CHD mediated by 9 polymorphisms in 6 different genes found such naturally random allocation to lower LDL-C was associated with a 55% lower risk of CHD for each mmol/l lower LDL-C, which is approximately three times greater than that observed from statin treatment started later in life (Ference et al. 2012).

Diabetes and metabolic syndrome. Diabetes mellitus is a major risk factor for CVD, and is associated with a greater risk for CHD, stroke, chronic kidney, and peripheral vascular disease (Kaseta and Sowers 2005). There are wide variations in prevalence according to gender and ethnicity. In 2011–2014, among US adults, the prevalence of physician-diagnosed diabetes mellitus was lowest in whites (7.4% in females and 8.0% in males) and highest in non-Hispanic Blacks (13.6% in females and 14.1% in males) (Benjamin et al. 2018).

More than three-fourths of those with diabetes die of cardiovascular complications, most notably myocardial infarction and stroke, although peripheral arterial disease and heart failure are among the most common initial first CVD manifestations in persons with diabetes. Given this point, the National Cholesterol Education Program designated diabetes as a CHD risk equivalent (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001) because the risk of CHD in those with diabetes without known heart disease had been shown to be similar to recurrent CHD events in those with CHD (but without known diabetes), although more recent studies are showing that this is not always the case, with recent meta-analyses showing those with diabetes (without CHD) have about half the risk of future CHD events as those with CHD (but without diabetes). Population-based studies such as Framingham show about a 2–3-fold greater risk of CVD events in men with diabetes as compared to men without diabetes, but that in women, the corresponding figure is a 3–7-fold greater risk.

Diabetes is typically diagnosed by a glycated haemoglobin (HbA1c) level of 6.5% or greater, fasting glucose $\geq$126 mg/dl (7 mmol/l) or glucose level of $\geq$200 mg/dl (11.1 mmol/l) from the non-fasting state or after a 2-hour post-load glucose challenge test (American Diabetes Association 2018a). Pre-diabetes is diagnosed by a fasting glucose of 100–125 mg/dl or casual glucose of 140–199 mg/dl.

Clinical trial evidence to show whether intensive glycaemic control in persons with diabetes lowers CVD event rates has shown mixed results. The United Kingdom Prospective Diabetes Study (UKPDS) originally showed a borderline, non-significant ($p = 0.052$) 16% reduction in risk of myocardial infarction among those with newly diagnosed type 2 diabetes who were treated with intensive glucose-lowering therapy, but the 10-year post-interventional follow-up of this study, which was recently published, showed

that these benefits continued with a 15% significant ($p = 0.01$) reduction in risk of myocardial infarction (Holman et al. 2008). A similar, extended post-interventional follow-up of the Diabetes Control and Complications Trial of Type 1 diabetes, which did not initially show a significant reduction in CVD events at the end of the randomized trial, showed years later a continued effect of the original intensive glucose-lowering treatment, with a 42% reduction in the risk of any cardiovascular event (The Diabetes Control and Complications Trial 2005). Such a continued post-trial effect of the randomized glycaemic therapy has been termed a 'glycaemic legacy' effect. More recently, however, three important randomized clinical trials (the Action to Control Cardiovascular Risk in Diabetes (ACCORD), ADVANCE and the Veterans Affairs Diabetes Trial (VADT)) failed to show that intensive glucose-lowering to a HbA1c range of 6–6.5%, significantly reduced CVD event rates, as compared to more standard maintenance of the HbA1c in the 7–9% range. In fact, those randomized to the intensive therapy group in ACCORD actually had a higher rate of CVD mortality (The Action to Control Cardiovascular Risk in Diabetes Study Group 2008), although this increased risk was restricted to those with prior macrovascular disease and where there was unsuccessful lowering of the glucose as a result of the intensive therapy. Those with less complicated diabetes (e.g. patients who were more recently diagnosed and without prior macrovascular disease) actually showed a benefit in the primary endpoint. Moreover, an important lipid substudy of ACCORD tested the efficacy of adding the fibric acid derivative fenofibrate or placebo to ongoing statin therapy and found no benefit in terms of reducing CVD event rates (although there was a benefit seen in the subgroup with high triglycerides and low HDL-C) (ACCORD Study Group 2000a). In addition, in the blood pressure substudy of ACCORD, intensive blood pressure therapy to achieve a systolic blood pressure <120 mmHg, as compared with <140 mmHg, was also found to provide no significant benefit in terms of CVD risk reduction, although there was a significant benefit in stroke reduction (ACCORD Study Group 2010b).

Most recently, however, newer diabetes agents, in particular recent trials of SGLT-2 inhibitors and GLP-1 receptor agonists have finally demonstrated benefit in cardiovascular outcomes trials. SGLT-2 inhibitors lower blood glucose by urinary excretion and have other positive benefits, such as on blood pressure, arterial stiffness, and weight/adiposity, and oxidative stress.

The first of these, empagliflozin, was tested in the EMPA-REG outcomes trial among persons with diabetes and established CVD, demonstrating a significant 14% reduction in the primary composite cardiovascular outcome, but a greater 38% reduction in cardiovascular death and 35% reduction in heart failure hospitalizations (Zinman et al. 2015). Later, the CANVAS trial involving canagliflozin showed a similar benefit in the primary composite cardiovascular outcome and in heart failure hospitalizations, but no significant benefit in cardiovascular mortality (Neal et al. 2017). GLP-1 receptor agonists are incretin-based therapies that stimulate insulin secretion and suppress glucagon secretion and may have other effects including reducing inflammation, blood pressure, body weight, and improving beta-cell function. The LEADER trial involving liraglutide is the first cardiovascular outcomes-driven trial of a GLP-1 reception agonist to show a benefit with a significant 13% reduction in the primary composite cardiovascular outcome (Marso et al. 2016).

While the concept of the metabolic syndrome has waned over recent years, this condition referring to a constellation of cardiometabolic risk factors that are associated with a greater risk of developing future diabetes and CVD has been useful for the purposes of defining those with multiple risk factors who may benefit from a more intensified, unified approach at risk factor modification. Studies have documented that 30–40% of adults have metabolic syndrome in the United States, with even higher prevalence rates in some regions such as in the Middle East. Certain definitions of the metabolic syndrome place insulin resistance or abdominal obesity as the necessary condition, with additional conditions including elevated blood pressure, low HDL-cholesterol, elevated triglycerides, and impaired fasting glucose making up the definition. The American Heart Association/National Heart Lung and Blood Institute definition (Grundy et al. 2005) requires the presence of at least three of the following five criteria: abdominal obesity defined by a waist circumference >35 inches in women or >45 inches in men; HDL-cholesterol <40 mg/dl in men or <50 mg/dl in women, fasting triglycerides $\geq$150 mg/dl; elevated blood pressure of $\geq$130 mmHg systolic or $\geq$85 mmHg diastolic or on hypertensive therapy; or impaired fasting glucose defined as $\geq$100 mg/dl (5.6 mmol/L) or on hypoglycaemic therapy. It is important to recognize that other definitions exist, such as that from the International Diabetes Federation which requires the presence of abdominal obesity as measured by lower waist circumference cut-off points in

European Caucasians (>94 cm in men and >80 cm in women), and among most Asian groups and those of Central and South American ancestry (where >80 cm in women and >90 cm in men define increased waist circumference) (Alberti et al. 2005).

Numerous studies have shown an increased risk of future CVD events in persons with the metabolic syndrome. Among United States adults (Malik et al. 2004), a stepwise increase in risk for CHD, CVD, and total mortality has been shown relating to the presence of metabolic syndrome alone, metabolic syndrome with diabetes or pre-existing CVD, and metabolic syndrome with both CVD and diabetes (Fig. 8.1.4).

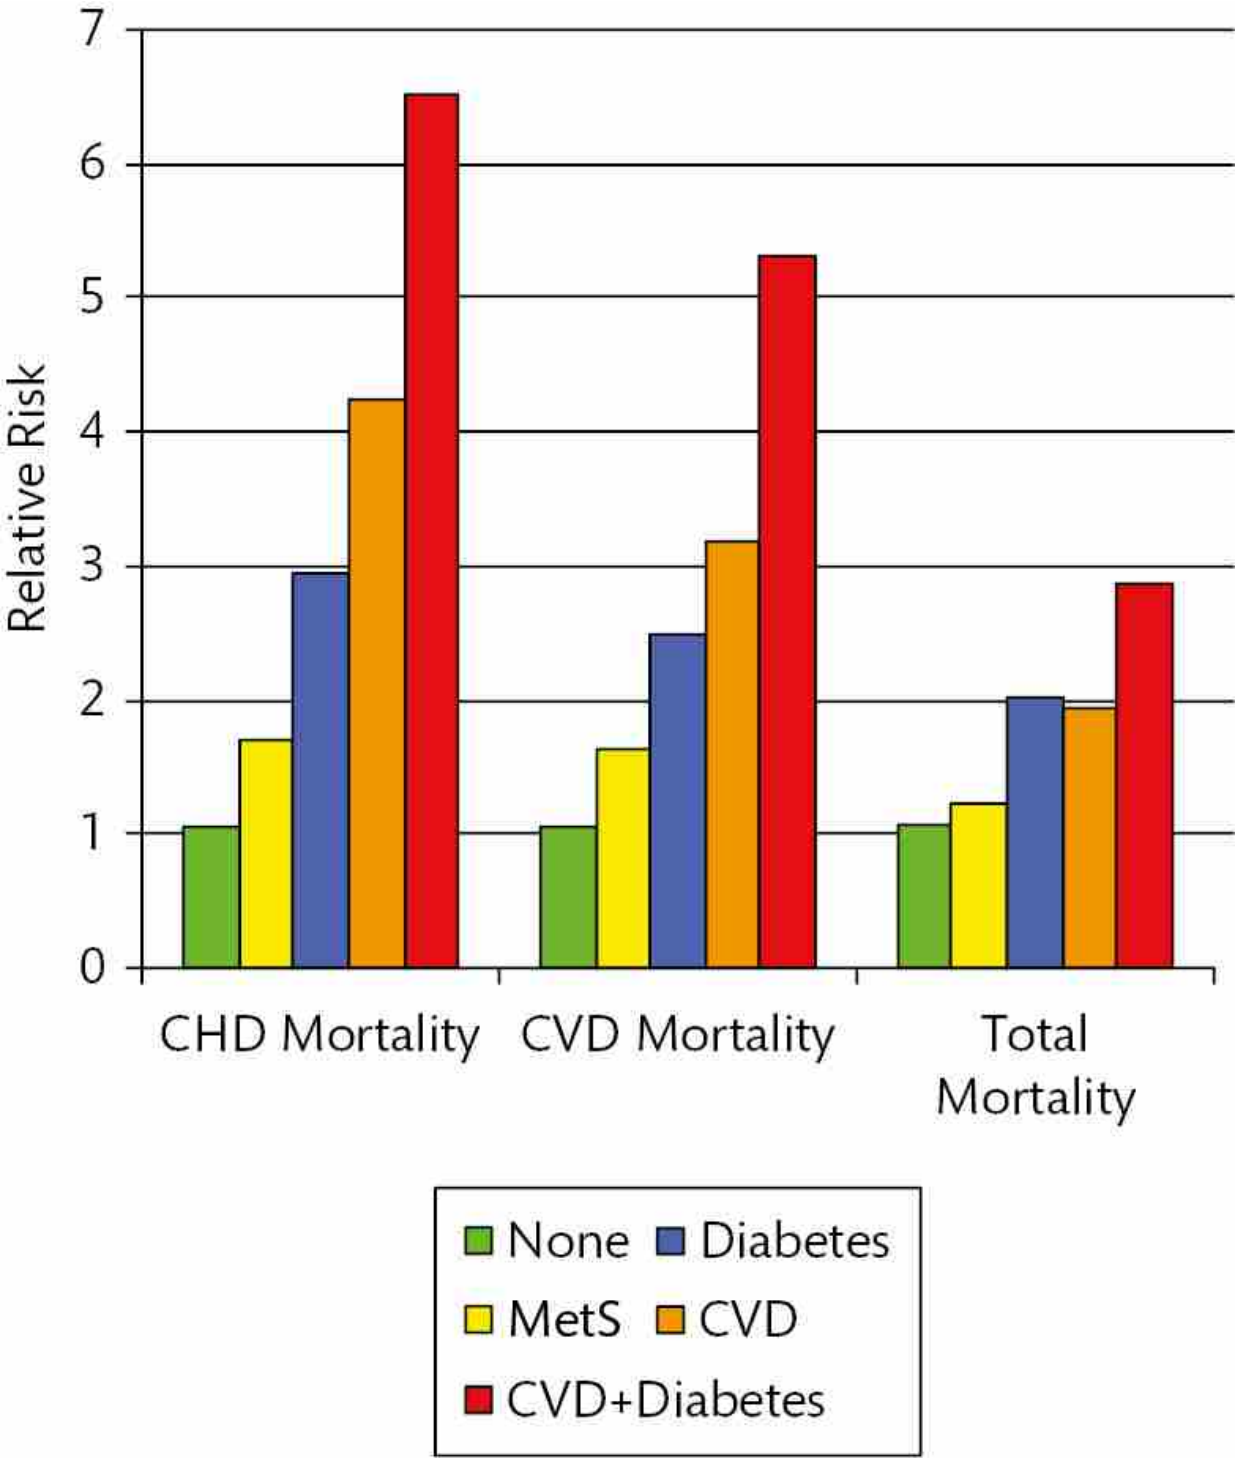

Fig. 8.1.4 Relative risks for mortality from coronary heart disease, cardiovascular disease, and all causes in United States Adults associated with the presence of metabolic syndrome with and without diabetes: NHANES II: 1976–80 follow-up study (mean 13 years follow-up).

From Malik S, Wong ND, Franklin SS, et al. Impact of the metabolic syndrome on mortality from coronary heart disease, cardiovascular disease, and all causes in United States Adults. *Circulation*; 2004: 110: 1239–44, with permission from Wolters Kluwer.

Hypertension. Elevated blood pressure, and particularly systolic blood pressure, is strongly and positively related to the risk of future CHD and stroke. Hypertension is currently defined as a systolic blood pressure of 130 mmHg or higher, diastolic blood pressure of 80 mmHg or higher (or on pharmacologic treatment to lower blood pressure). Levels of 130–139 mmHg systolic or 80–89 mmHg diastolic are defined as Stage 1 hypertension, and levels of 140 mmHg or higher systolic or 90 mmHg or higher diastolic are defined as Stage 2 hypertension based on the new 2017 ACC/AHA guidelines (Whelton et al. 2018). Based on US NHANES data from 2011 to 2014, this results in the identification of 45.6% of US adults (103.3 million) with hypertension, of which 36.2% (81.9 million) would be recommended for treatment, and among those treated 53.4% (29.2 million) would still be above target blood pressure goal (Muntner et al. 2018). There is a strong age-related increase in prevalence of hypertension, and based on the older cut-point of 140/90 mmHg, prevalence ranges from under 10% in those <35 years of age and progressively increases with age to more than 70% in those aged 75 years and over with higher prevalences in men before age 55, but higher prevalences in women after age 65 (reaching 81.2% among those aged 75 years and over). Of note, isolated diastolic hypertension (systolic blood pressure of <140 mmHg but diastolic blood pressure of 90 mmHg or higher) is the most common form of hypertension under age 50, while isolated systolic hypertension (systolic blood pressure of 140 mmHg or higher, but diastolic blood pressure <90 mmHg) predominates over the age of 60 years (Franklin et al. 2001).

For every blood pressure increase of 20/10 mmHg (systolic/diastolic) above 115/75 mmHg, the risk of death from CHD, stroke, or CVD doubles. Numerous clinical trials have shown that lowering blood pressure substantially decreases the risk of future cardiovascular events, stroke, and end-stage renal disease. A large meta-analysis of active treatment (with initial low dose diuretic, beta blocker, ACE inhibitor or calcium antagonist) compared to placebo showed significant reductions in the risk for heart failure (36%), stroke (33%), CHD (16%), CVD death (15%), overall CVD (25%) and total mortality (12%) (Prospective Studies Collaborative 2002; Elliott 2005). Of note, the recent landmark Systolic Blood Pressure Intervention Trial (SPRINT) showed those non-diabetic but higher cardiovascular risk participants targeted to a systolic blood pressure <120 mmHg compared to <140 mmHg (with actual achieved blood pressures of

121 mmHg and 136 mmHg, respectively) was stopped early due to definitive benefit with the intervention group showing a 25% reduction in the primary composite CVD endpoint with a substantial 38% reduction in heart failure hospitalization and 43% reduction in cardiovascular mortality. All-cause mortality was also significantly reduced by 27% (SPRINT Research Group et al. 2015).

Dyslipidaemia. Increased levels of total and low density lipoprotein (LDL)-cholesterol have long been recognized as major risk factors for CHD. A direct curvilinear relation exists between total and low density lipoprotein (LDL)-cholesterol and the risk of CHD. For example, compared to those with total cholesterol levels of 200 mg/dl, those with levels of 240 mg/dl are at approximately twofold greater risk, while those with levels of 300 mg/dl have a fourfold increased risk. However, there is significant overlap in total or LDL-cholesterol levels between those who experience CHD events versus those who do not and approximately one-third of heart attacks occur in persons with “normal” levels of total cholesterol below 200 mg/dl. Importantly, a low level of high density lipoprotein-cholesterol (typically defined as <40 mg/dl in men and <50 mg/dl in women), regardless of level of total cholesterol, is strongly associated with an increased risk of CHD (Castelli et al. 1986). For example, across levels of total cholesterol from <200 mg/dl to ≥260 mg/dl, the 14-year incidence of CHD varies only from 11.2 to 12.5%, whereas when HDL-C >60 mg/dl, these rates are 3.7% to 3.8%, respectively.

Table 8.1.1 Prevalence of elevated total and LDL-cholesterol and low HDL-cholesterol by gender and ethnicity, US adults aged 20 years and over, National Health and Nutrition Examination Survey 2011–2014

Population	Total cholesterol ≥200 mg/dl	Total cholesterol ≥240 mg/dl	LDL-cholesterol ≥130 mg/dl	HDL-cholesterol <40 mg/dl
All	39.7%	11.9%	30.3%	18.7%
Males	37.0%	10.6%	30.0%	27.9%
Females	42.0%	13.0%	30.4%	10.0%
White males	37.0%	10.8%	29.3%	28.4%
White females	43.4%	13.8%	32.1%	10.3%
Black males	32.6%	7.3%	29.9%	20.7%
Black females	36.1%	9.6%	27.9%`	8.0%
Mexican-American males	43.1%	13.6%	36.6%	30.7%
Mexican-American females	41.2%	12.5%	28.7%	11.8%
Asian males	39.9%	10.8%	29.2%	25.0%
Asian females	40.5%	11.2%	25.0%	6.7%

Source: data from Benjamin EJ, Virani SS, Callaway CW, et al. American Heart Association Council on Epidemiology and Prevention Statistics Committee and Stroke Statistics Subcommittee. Heart Disease and Stroke Statistics-2018 Update: A Report from the American Heart Association. Circulation. 2018; 137(12):e67–e492.

Other lipid abnormalities include elevated serum triglyceride levels (the normal level is considered to be <150 mg/dl), small particle size LDL-cholesterol (known as small dense LDL-cholesterol) and elevated lipoprotein (a) levels. There has also been recent interest in non-HDL-cholesterol since it captures all the atherogenic apolipoprotein B-containing lipoproteins and does not require, unlike LDL-cholesterol, measurements to be made after fasting. Several epidemiological studies have demonstrated a stronger relationship of non-HDL-C compared to LDL-cholesterol with incidence of CHD.

Table 8.1.1 shows the prevalence of elevated total and LDL-cholesterol and low HDL-cholesterol levels among US adults aged 20 years and over in 2011–2014 (Benjamin et al. 2018).

Numerous primary and secondary prevention clinical trials have documented the efficacy of lowering LDL-cholesterol, particularly with HMG-CoA reductase inhibitor drugs ('statins'), which can lead to approximately 25–35% reductions in CHD and CVD incidence, where the lower the LDL-C achieved, the lower were the event rates (Rosensen 2004). These trials also showed no threshold level of LDL-C reductions where the CVD event rates begin to flatten. A large meta-analysis of 14 statin trials comprising 90,056 subjects showed that over a 5-year treatment period, every mmol/L reduction (approximately 40 mg/dl) in LDL-cholesterol achieved, was associated with reductions in all-cause mortality of 12%, coronary mortality of 18%, myocardial infarction and CHD death of 23%, stroke incidence of 17%, all major vascular events of 21%, and with no difference (relative risk 1.00) in cancer incidence (Baigent et al. 2005). Importantly, several trials have shown the additional benefit of reducing the LDL-C, with high dose statin therapy, to levels below 100 mg/dl. The largest of these, the Treat to New Targets (TNT) study showed that the achieved LDL-C of 77 mg/dl with high dosage atorvastatin therapy, when compared to achieved LDL-C of 101 mg/dl with low dose atorvastatin therapy, resulted in an additional 22% reduction in major cardiovascular events (LaRosa et al. 2005).

Given that most randomized clinical trials of LDL-C lowering have demonstrated no more than 40% reductions in CVD incidence, addressing the remaining 'residual' risk has been of great interest. One factor that has been specifically investigated has been whether the raising of HDL-C levels will provide further benefit in reducing CVD events beyond that afforded by LDL-C lowering, given the strong protective effect of increased HDL-C levels suggested by observational studies. The AIM-High Trial (AIM-HIGH Investigators et al. 2011) was designed to be a rigorous test of the HDL hypothesis, randomizing 3,414 men and women with a prior CVD event and low HDL-C, and who had well-controlled LDL-C levels averaging 74 mg/dl on a statin, to extended-release niacin or placebo. LDL-C levels were kept similar between the groups, and the on-treatment HDL-C level averaged 5 mg/dl higher in those on niacin. However, the trial was discontinued early due to futility, with no significant reduction in CVD events observed (HR =

1.02, p = 0.79). The failure of this trial, as well as that of a second much larger niacin trial, HPS2-Thrive as well as the failure of three of four major trials of cholesterol ester transferase protein (CETP) inhibitors have raised significant questions as to the benefit of raising HDL-C levels, particularly in patients who are already well-controlled on statins.

In recent years, evidence has accumulated regarding the cardiovascular benefits of newer non-statin therapies. In the IMPROVE-IT trial of persons with a recent (within 10 days) acute coronary syndrome, the addition of the cholesterol absorption inhibitor ezetimibe to simvastatin compared to simvastatin alone resulted in a 6% relative risk reduction for the primary composite cardiovascular endpoint, although given the high-risk study population, the absolute risk reduction was 2%, resulting in a number needed to treat of 50 for the prevention of a CVD event (Cannon et al. 2015). In addition, with the availability of proprotein convertase subtilisin kexin type 9 (PCSK9) monoclonal antibody therapies evolocumab and alirocumab, which provide average 50–60% reductions in LDL-C above maximal tolerated statin therapy, recently reported cardiovascular outcomes trials (Sabatine et al. 2017; American College of Cardiology 2018) have demonstrated further 15% relative risk reductions for the composite CVD endpoint, with greater benefit being observed with time and in those with higher risk features (e.g. more recent myocardial infarction or number of prior cardiovascular events).

Cigarette smoking. Tobacco smoking is among the leading preventable causes of death globally. Numerous studies have linked tobacco use to the incidence of, and mortality from, CVD, with approximately a half-million deaths annually in the United States being attributed to tobacco use. Further, environmental tobacco smoke (‘second-hand smoke’) is responsible for approximately 40,000 deaths from heart disease annually in the United States. Cigarette smokers are 2 to 4 times more likely to develop CHD than non-smokers. Also, their risk of stroke is doubled and risk for peripheral vascular disease is more than 10 times higher than that of non-smokers (Luepker and Lando 2005). The most recent data among US adults in 2015 show an overall prevalence of smoking of 15.1%, with a wide variation by ethnic groups, ranging from 7% in Asian to 21.9% in American Indian/Alaska Natives (Benjamin et al. 2018).

Obesity and physical inactivity. Recent estimates showed that two-thirds of US adults are overweight or obese (body mass index of 25 kg/m^2 or

higher), with 30% being obese (body mass index of 30 kg/m^2 or higher). Since the 1960s, there has been a dramatic nearly threefold increase in obesity prevalence among men from 10.7% to 34.4% and more than a twofold increase in women from 15.7% to 36.1%. Moreover, 17.4% of children aged 6–11 and 20.6% aged 12–17 are defined to be obese based on latest survey data from NHANES 2013–2014. Further recent estimates from NHIS 2015 showed that half (49.7%) of the US adult population (52.9% of men and 46.7% of women) met nationally recommended amounts of physical activity (150 minutes of moderate, or 75 minutes of vigorous activity or an equivalent combination per week) (Benjamin et al. 2018).

Obesity has been shown by numerous studies to be associated with an approximate 1.5- to 2-fold increase in risk of death from CHD, with the increase in risk beginning below the 25 kg/m^2 cut-off point for overweight. Numerous studies also show approximately 20–40% lower risks of mortality and cardiovascular events associated with increased levels of physical activity or measured fitness. Several cardiovascular risk factors are linked to obesity, including hypertension, dyslipidaemia (including low HDL-cholesterol levels), type 2 diabetes, obstructive sleep apnoea, and hyperinsulinemia. Increases in physical fitness have also been shown to be linked to increases in HDL-cholesterol levels and reductions in systolic and diastolic blood pressure, insulin resistance, and glucose intolerance. Abdominal obesity, most commonly indicated by a waist circumference of >40 inches in men or >35 inches in women, is a major component of the metabolic syndrome (McCowen and Blackburn 2005). *Measures of cardiovascular health and CVD risk*. In recent years, the American Heart Association (AHA) (Benjamin et al. 2018) has promoted a goal to improve the cardiovascular health of all Americans by 20% while reducing mortality from heart disease and stroke by 20% by the year 2020. These goals introduce the concept of promoting cardiovascular health which is more positive and motivating than the concept of preventing *cardiovascular disease*, and have focused on examining the proportion of individuals (and the relation to CVD risk) who achieve one or more “ideal levels” based on the following seven metrics (also known as AHA’s Life’s Simple Seven™): (1) cigarette smoking (non-smoking is ideal); (2) physical activity (150 minutes or more moderate intensity or equivalent exercise per week is ideal); (3) body mass index (<25 kg/m^2 is ideal); (4) healthy diet (achieving at least 4 of 5 key dietary components focusing on fruit/vegetable, fish, fibre, and

sodium intake and sweetened beverage intake); (5) cholesterol (<200 mg/dl ideal in adults, <170 mg/dl in children), 6) blood pressure (<120/80 mmHg is ideal); and (7) fasting plasma glucose (<100 mg/dl is ideal). Fewer than 20% of adults and only about 40% of children meet five or more of these criteria for ideal cardiovascular health and fewer than 1% of adults are at ideal levels of all seven metrics of cardiovascular health. Moreover, CVD incidence varies more than 10-fold according to the number of cardiovascular health behaviours and factors that are present (Folsom et al. 2011) (Fig. 8.1.5).

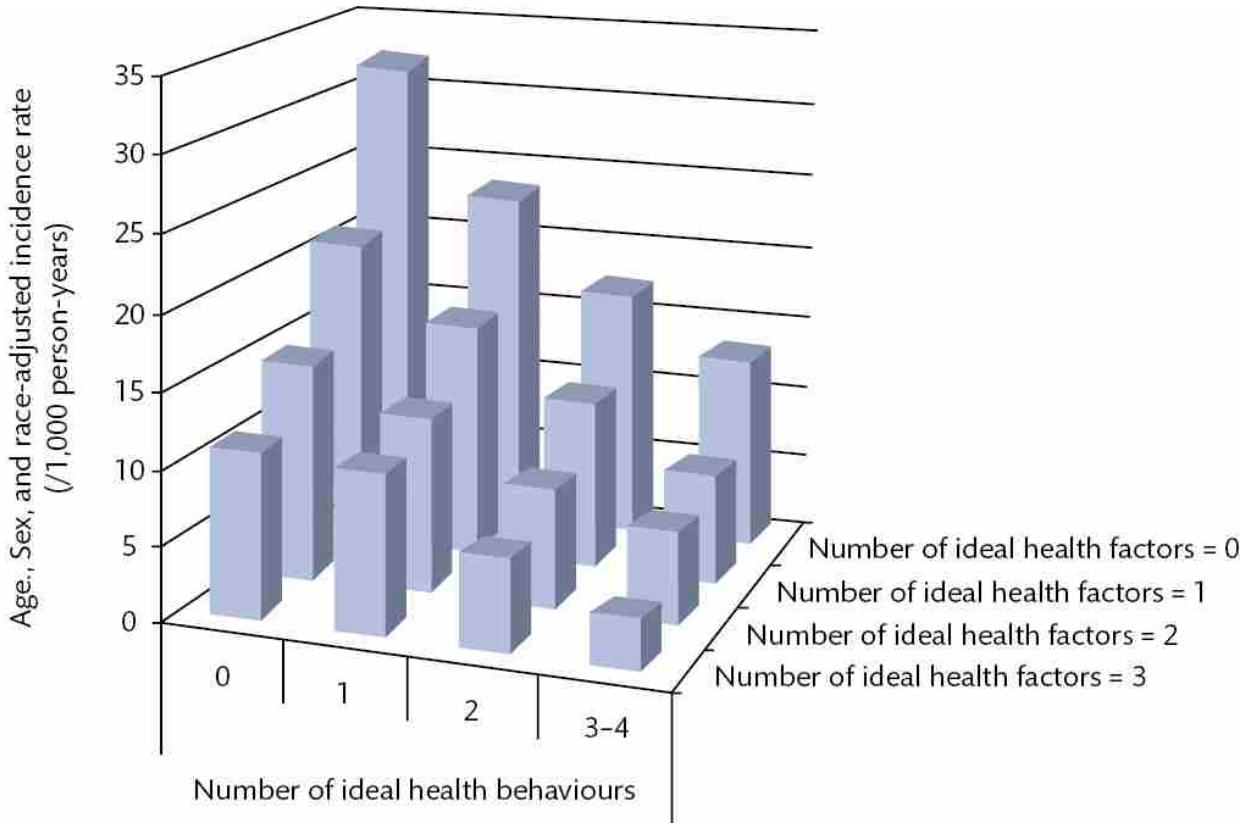

Fig. 8.1.5 Incidence of CVD according to the number of ideal health behaviours and health factors. Reprinted from Folsom AR, Yatsuya H, Nettleton JA, et al. Community prevalence of ideal cardiovascular health by the American Heart Association definition and relation with cardiovascular disease incidence. *J Am Coll Cardiol* 2011; 57: 1690–6 with permission from Elsevier.

Risk factors for stroke

Important risk factors for stroke include elevated blood pressure, diabetes mellitus, disorders of heart rhythm, low HDL-cholesterol, cigarette smoking, family history, and chronic kidney disease (WHO 2011). Elevated blood pressure is the most important risk factor for both ischaemic stroke and intracranial haemorrhage, with about 77% of those with a first stroke having a blood pressure of 140/90 mmHg or higher. The Framingham Heart Study demonstrated the importance of mid-life antecedent hypertension as well as systolic hypertension as important predictors of stroke (Romero and Wolf 2013). Even prehypertension is associated with incident stroke. Randomized clinical trials consistently show the efficacy of blood pressure control for prevention of stroke. Diabetes is also a strong predictor of stroke, although mainly before age 55 years of age in blacks and before age 65 years of age in whiles. Atrial fibrillation is another powerful risk factor for stroke, independently increasing risk approximately fivefold at all ages, with nearly one-quarter of strokes attributable to atrial fibrillation in the ninth decade of life. While elevated total cholesterol levels are not strongly predictive of stroke, some studies have found low HDL-cholesterol levels to predict risk, but clinical trials of statin therapy consistently show benefits of such therapy for preventing stroke. Prospective studies have also shown moderate to vigorous physical activity to be associated with an overall 35% reduction in risk of ischaemic stroke compared with no physical activity. A family history of parental ischaemic stroke before the age of 65 has also been shown to be associated with a threefold increase in ischaemic stroke in offspring, even after adjustment for other risk factors. Finally, increased levels of creatinine and reduced glomerular filtration rate (eFGR) have been shown to predict future stroke and symptoms.

Risk factors for heart failure

Hypertension is among the most prominent of risk factors for heart failure, followed by a preceding myocardial infarction, elevated B-type natriuretic peptide levels, and urinary albumin-to-creatinine ratio. In the Physicians Health Study, the lifestyle risk of heart failure was greater in those with hypertension and less in those with healthy lifestyle factors, including normal weight, not smoking, regular exercise, moderate alcohol intake, consumption of breakfast cereals, fruits, and vegetables (Djousse et al. 2009). The Framingham Heart Study was key in demonstrating the poor

prognosis associated with heart failure in the community, with 1 of 2 individuals dying within 5 years of diagnosis and the strong association of hypertension conferring nearly an eightfold risk in men and fourfold risk in women for developing heart failure. They also documented other predictors of new onset heart failure, including elevated plasma natriuretic peptide levels, asymptomatic left ventricular systolic dysfunction, and increased left ventricular diastolic dimension (Mahmood and Wang 2013).

Risk factors for peripheral arterial disease

Peripheral arterial disease shares many of the same risk factors that coronary heart disease does, although diabetes and cigarette smoking are stronger risk factors for peripheral arterial disease than for coronary heart disease with odds ratios in the range of 3 to 4. Another study showed hypertension, diabetes, chronic kidney disease, and smoking were associated with incident peripheral arterial disease. Meta-analysis of 16 cohort studies indicated people at with low ankle brachial index (ABI) (<0.9) had around threefold risk of all-cause death as well as cardiovascular death in both sexes.

Cardiovascular disease risk assessment

Global risk scores for cardiovascular disease risk assessment. In order to understand an individual's risk of CVD or CHD, it is important to understand an individual's "global risk" of developing the condition. Most risk scores developed over the past few decades, including those from the Framingham Heart Study in the United States as well as those from other countries have involved the determination of the future risk of developing CHD in the next 10 years. These have been used to stratify a person's risk for consideration or intensification of risk factor management, especially for lipid-lowering therapy. More recently, algorithms for total CVD risk from Framingham have been developed, which are more global as they incorporate the combined risk for CHD, stroke, heart failure, and peripheral arterial disease (D'Agostino et al. 2008). In late 2013, the ACC/AHA released the pooled cohort risk calculator, which allows for the prediction of 10-year risk (in those aged 40–79 years of age) and lifetime risk (in those aged 20–59 years of age) of atherosclerotic cardiovascular disease (ASCVD)

comprising of non-fatal or fatal myocardial infarction or stroke (Goff et al. 2014), and which is currently the standard for risk assessment recommended today for clinical practice.

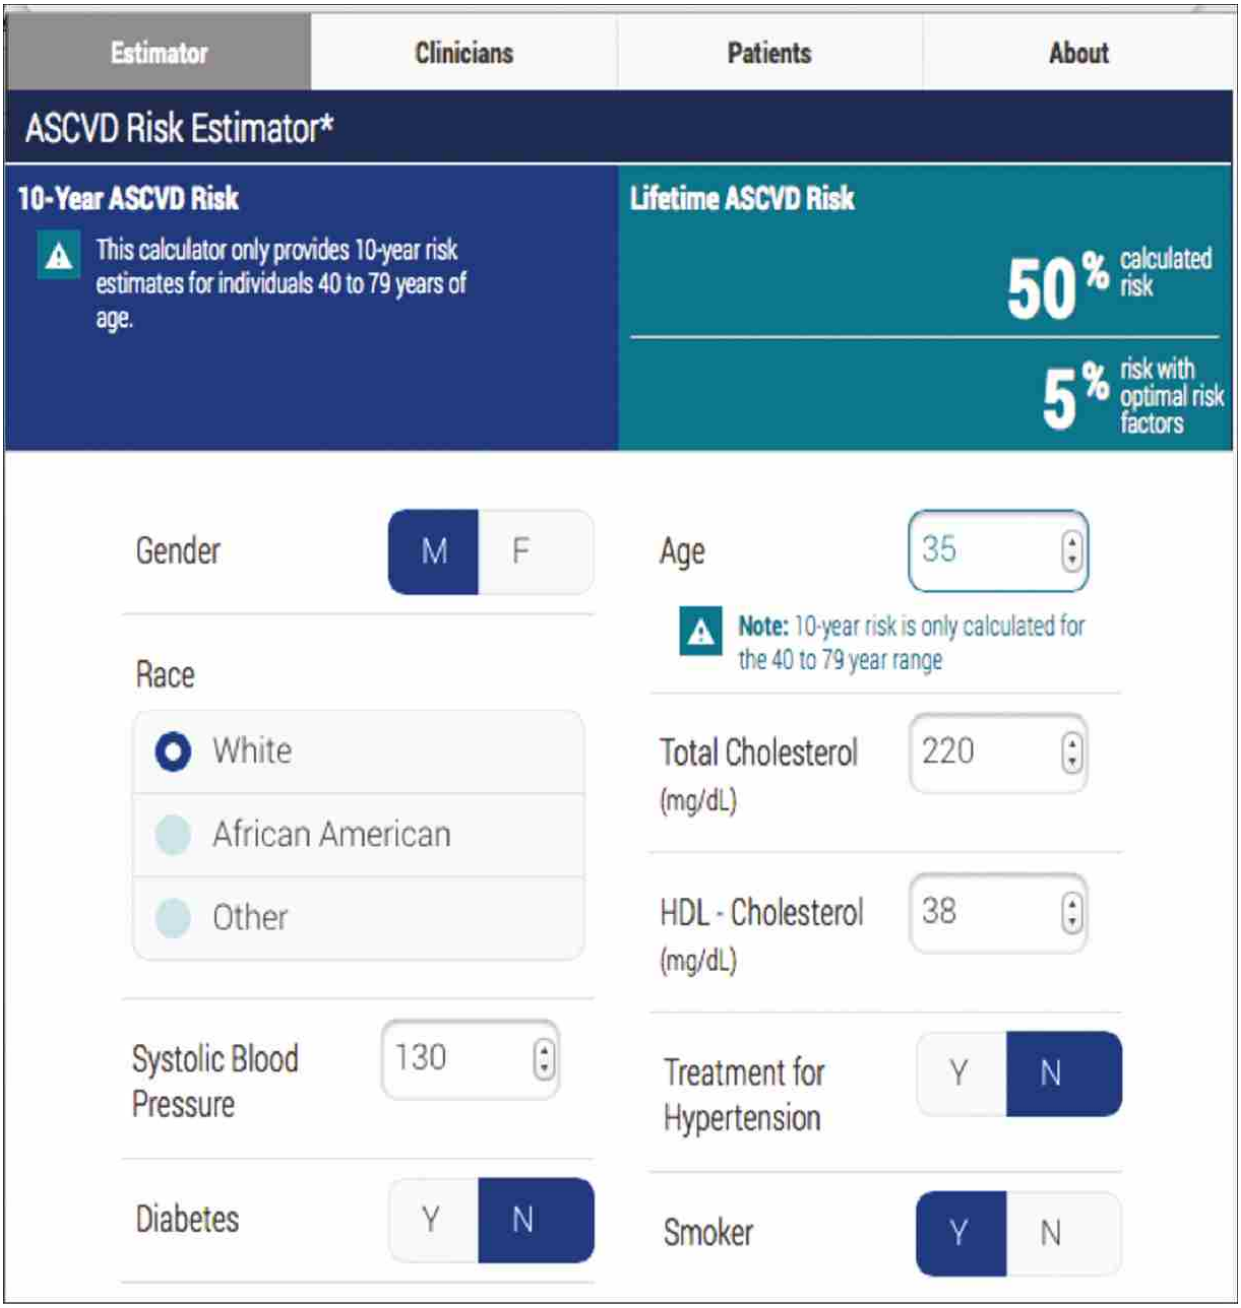

Fig. 8.1.6 Pooled cohort risk calculator.
From https://clincalc.com/cardiology/ascvd/pooledcohort.aspx.

In those where a global risk estimate is obtained, depending on the risk status, the appropriate intensity of treatment for given risk factors is considered (see next under cholesterol management). While estimation of global risk as described earlier is recommended, it may be best considered a starting point in risk assessment and a strong emphasis is to use the risk calculator as part of the patient-clinician 'risk discussion' on the best ways to lower cardiovascular risk through both lifestyle and use of appropriate preventive therapies. In addition, the presence of other risk factors not included in the risk algorithms, such as abdominal obesity, elevated triglycerides (if severe enough), impaired fasting glucose, or a strong positive premature family history, if present, however, could be used by the clinician to stratify an individual's risk or required intensity of treatment upward. The ACC/AHA 2014 Guideline on Cardiovascular Risk Assessment (Goff et al. 2014) specifically notes that if the treatment decision is uncertain on the basis of the risk calculator that the following additional measures can be used for consideration to further inform the treatment decision: (1) family history of premature CVD (which should always be done as part of patient evaluation); (2) high-sensitivity C-reactive protein (with a level of >2 mg/L indicating higher risk); (3) coronary calcium scoring (with a score of >300 mg/dl or >75th %tile for age and sex warranting a high risk level); or (4) ABI (with a level of <0.9 indicating higher risk and diagnostic of peripheral arterial disease) (see next).

Inflammatory measures for cardiovascular disease risk. High levels of inflammatory markers, including high-sensitivity C-reactive protein (hs-CRP), a marker of systemic inflammation, as well as lipoprotein phospholipase associated A2 (LpPla2), a measure of vascular inflammation have been shown in numerous studies to be independently related to the risk of future cardiovascular events. IL-6, other interleukins, myeloperoxidase, and tumour necrosis factor-alpha (TNF-alpha) also have inflammatory activity and have been shown to be associated with cardiovascular events in some studies, as have other biomarkers such as brain naturietic peptide (BNP) and troponin levels. Levels of C-reactive protein exceeding 2 mg/L have been recommended as a higher risk level that could inform the treatment decision beyond global risk scoring (Goff et al. 2014). There are no current recommendations for the measurement of other inflammatory markers or biomarkers for the assessment of CVD risk in asymptomatic adults, however. The recent CANTOS trial recently provided proof of

concept for the role of reducing/modifying inflammation in high risk individuals for the reduction of CVD events (Ridker et al. 2017). In this trial, high risk persons with known CVD were randomly assigned on top of optimal treatment to the monoclonal antibody to Il-1β, canakinumab for a median follow-up of 3.7 years and showed a significant 15% relative risk reduction in the primary CVD endpoint.

Subclinical cardiovascular disease assessment. The ability to image or directly measure the atherosclerotic burden has been of great interest but whether these measures provide added value over less expensive and easier traditional office-based risk factor measures (including global risk assessment scores) has been an important question in cardiovascular epidemiology and prevention over the past 15 years (Greenland et al. 2010). Such measures must have a high level of sensitivity and specificity for detection of the disease, must be reproducible and cost-effective, and should provide added clinical utility over current office-based risk assessment.

Increased carotid intima medial thickness (CIMT) as measured from carotid B-mode ultrasound, has been shown to be related to the risk of future CVD events from numerous prospective epidemiologic studies over the past 25 years, including the Atherosclerosis Risk in Communities (ARIC), Cardiovascular Health Study (CHS), and the Multiethnic Study of Atherosclerosis (MESA). CIMT has also been used as a surrogate endpoint in numerous clinical trials involving lipid-lowering and other interventions. Moreover, the presence of carotid plaques provides additional information and together with CIMT measurements have modest clinical utility for reclassification of risk in asymptomatic intermediate risk adults. While the most recent ACC/AHA Guidelines on Cardiovascular Risk Assessment do not recommend the measurement of CIMT alone for the assessment of CVD risk (Goff et al. 2014), due to its modest improvement in risk prediction from recent meta-analyses, more recent European guidelines have emphasized the assessment of carotid plaque together with CIMT.

ABI measured from ankle and arm blood pressures utilizing a Doppler, provides for an assessment of peripheral arterial disease, which is diagnosed to be present when the ABI is less than 0.9. A low ABI has also been shown to be related to increased total and CVD mortality in numerous observational studies. However, as ABI tends not to be low until after the age of 60 years, it is therefore most useful as a screening tool for peripheral arterial disease in older persons. It is also a recommendation for further informing the

treatment decision if uncertain from global risk assessment alone (Goff et al. 2014).

Measures of coronary artery calcium as assessed by computed tomography (CT), have been shown in numerous prospective studies, to be associated with the future risk of CHD and CVD events, independent of standard risk factors (Greenland et al. 2010). Coronary calcium measures also provide incremental predictive value and added reclassification of risk over global risk assessment for the prediction of cardiovascular events. In the MESA study, it has been shown to provide greater incremental risk prediction among intermediate risk individuals (from C-statistic improvement) than any other major biomarker or subclinical disease screening test (Detrano et al. 2008). CAC testing is also felt to be the most useful of the current approaches for improving risk assessment in intermediate risk subjects (Goff et al. 2014).

There are also numerous other tests which have varying levels of evidence relating them to CVD event risk. These include assessments of endothelial function, pulse wave velocity, brachial artery reactivity, and imaging of soft plaque such as by CT coronary angiography. Most of these other tests, however, do not have the quantity, strength, or consistency of evidence that CIMT, ABI, or CAC assessment do, and hence there is not the same level of consensus for recommending their use for the screening of asymptomatic adults.

Preventive strategies for cardiovascular disease risk reduction

Cardiovascular epidemiology and disease prevention encompass an extensive field investigating the distribution and variation of CVD conditions, most notably coronary heart disease and stroke, their risk factor determinants, and strategies at the population and individual level aimed at preventing the development or recurrence of CVD. Epidemiologic approaches to studying CVD provide us with the tools for preventive efforts at the individual and population level. *Primordial prevention* is aimed at prevention of the risk factors for CVD, such as efforts aimed to prevent hypertension, obesity, or dyslipidaemia. *Primary prevention*, which focuses on the modification of these and other known risk factors, is aimed at preventing the clinical manifestations of CVD, such as myocardial infarction and stroke. *Secondary prevention* focuses on those who already have

manifestations of disease, but where aggressive control of risk factors can have a major impact in preventing recurrences of disease. Concerted efforts between governmental agencies, the community, and the private sector are required to best address the continuing epidemic of CVD.

Preventive strategies can be considered using the 'ABCDE' approach addressing aspirin/antiplatelet therapy (A), blood pressure and hypertension (B), cholesterol and dyslipidaemia (C), diet and nutrition (D), and exercise and physical activity (E). For secondary prevention among persons with pre-existing CVD, guidelines have been published by the American Heart Association/American College of Cardiology (Smith et al. 2011).

Aspirin and Antiplatelet Therapy. Aspirin prophylaxis (81–162 mg/day) has been recommended for persons at intermediate risk, for the prevention of CHD in men and prevention of stroke in women, including those with diabetes or metabolic syndrome. Additionally, among those with pre-existing CVD, aspirin is recommended in combination with clopidogrel due to the added benefit in prevention of secondary events. The use of alternative antiplatelet therapies is also discussed (Smith et al. 2011).

Blood pressure control. The most recent AHA/ACC guidelines (Whelton et al. 2018) have recommended the standard blood pressure goal of treatment of those with hypertension to be <130/80, with consideration of a diuretic, calcium channel blocker, or ACE inhibitor/ARB as the initial therapy in most patients, with the recommendation to add a second agent, including as a fixed-dose combination as needed to reach goal, especially when the blood pressure exceeds 20 mmHg systolic or 10 mmHg diastolic from target. Such pharmacologic treatment is recommended in most persons with hypertension at or above 140/90 mmHg, or 130/80 mmHg when the 10-year ASCVD risk from the pooled cohort risk calculator is at 10% or greater, thus persons between these numbers need such an assessment of their ASCVD risk. These recent guidelines also place a greater emphasis on home or ambulatory blood pressure monitoring for the evaluation of possible white coat or masked hypertension.

Cholesterol and lipid control. The 2014 ACC/AHA Guideline for the Management of Blood Cholesterol (Stone et al. 2014) has emphasizes defining four 'statin eligible' groups of patients: those with (1) clinical ASCVD; (2) LDL-C of 190 mg/dl or greater; (3) diabetes; and (4) 10-year ASCVD risk of 7.5% or greater based on the pooled cohort risk calculator. It has specifically removed LDL-C targets that were present in prior guidelines

because of the lack of clinical trial evidence for the use of such targets. Instead, the focus is on adequate intensity of statin medication, where for those with clinical ASCVD <75 years of age, LDL-C of 190 mg/dl, or diabetes and a 10-year ASCVD risk of 7.5% or greater, a high intensity statin is recommended with the expectation of a 50% or greater LDL-C reduction. In older persons with ASCVD, diabetes with <7.5% 10-year risk of ASCVD, or primary prevention subjects of 10-year ASCVD risk of 7.5% or greater, a moderate intensity statin is suitable. A recent non-statin consensus pathway update to these guidelines (Lloyd-Jones et al. 2017) has provided further guidance as to when these 'targets' of percentage (e.g. ≥50%) LDL-C reduction or specific values (e.g. <70 mg/dl in higher risk persons) have not been achieved that non-statin therapies such as ezetimibe or PCSK9 monoclonal antibody therapy can be recommended.

Cigarette smoking prevention and intervention. Smoking cessation has long been documented to reduce the risk of CVD. The risk of CHD is reduced by 50% within one year of smoking cessation and to that of a never-smoker within 15 years. It is recommended that at each consultation with a healthcare provider the visit should be used as an opportunity to address the 5A's of smoking cessation counselling which include 'Ask' (assess tobacco use at every visit); 'Advise' (strongly urge quitting); 'Attempt' (try to identify smokers ready to quit); 'Assist' (aid the patient in quitting); and 'Arrange' (for follow-up contacts). Interventions for smoking are varied. For youth, school, and community-based prevention programmes, state, and federal initiatives, as well as cessation assistance are available. For adults, behavioural treatment, self-help approaches, and pharmacologic therapy are used, with varying levels of success. For example, quit rates vary from 6% with physician advice only to 40% in those who participate in group programmes (40).

Diabetes control. Recommendations for the treatment of diabetes to optimize cardiovascular risk reduction is available from a variety of sources. For example, the latest recommendations from the American Diabetes Association (2018b) addresses antiplatelet therapy, glycaemic control, blood pressure control, lipid control (discussed earlier), weight control, and lifestyle management. Moreover, similar guidelines have been published by the European Association for the Study of Diabetes (EASD). Multifactorial intervention focusing on lipid, blood pressure, and glycaemic control has been shown to decrease the risk of future CVD events by more than 50%

(Gaede et al. 2008). This is a very important message given that in recent reports, only one tenth of those with diabetes have achieved target treatment levels for HbA1c, blood pressure, and LDL-C (Wong et al. 2012). While the goal of glycaemic control is a HbA1c level of less than 7% in most uncomplicated diabetics, and even 6–6.5% if achievable without side effects, given the results of recent trials, HbA1c levels of <8% are accepted as an appropriate goal for those with pre-existing micro or macrovascular disease or difficult-to-control diabetes (American Diabetes Association 2018b). Appropriate intensity statin therapy similar to the ACC/AHA guidelines discussed earlier is also considered appropriate. In addition, in persons requiring additional HbA1c reduction beyond initial therapy (especially when 9% or greater), for those with known ASCVD, these most recent ADA guidelines recommend the use of a drug shown to have cardiovascular outcomes benefit such as empagliflozin, canagliflozin, or liraglutide (although possible benefit is considered for metformin and pioglitazone).

Obesity management. The ACC/AHA/Obesity Society guideline for the management of overweight and obesity (Jensen et al. 2014) provides guidelines for maintaining ideal body weight. In particular, it notes even modest weight reduction can have beneficial effects on many of the cardiometabolic risk factors. It also recommends up to 14 sessions with a lifestyle interventionalist to provide maximum benefit in terms of weight reduction.

Exercise and physical activity. The recent ACC/AHA Guideline on Lifestyle Management (Eckel et al. 2014) recommends 150 minutes per week of moderate intensity physical activity in at least 3–4 sessions per week each lasting approximately 40 minutes, for LDL-C and blood pressure reduction. Regular physical activity can help maintain healthy blood pressure, weight, lipid levels, low levels of inflammation (C-reactive protein) and insulin sensitivity. A pedometer can be an effective tool for intervention with one guideline, for example, recommending walking at least 10,000 steps a day. For secondary prevention, a prescribed exercise programme is recommended, and participation initially in a supervised cardiac rehabilitation programme is advised for those recovering from a recent CHD event.

Food and nutrition. Lifestyle management remains the cornerstone for reducing CVD risk including achieving and maintaining optimal risk factor levels. The ACC/AHA Guideline on Lifestyle Management (Eckel et al.

2014) recommends the consumption of a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, non-tropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meats. It notes this dietary pattern should be adapted to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes) and to consider following plans such as the Dietary Approaches to Stop Hypertension (DASH) dietary pattern, the US Department of Agriculture (USDA) Food Pattern, or the AHA Diet. It is also recommended to consume no more than 6% calories in saturated fat, and to avoid when possible the intake of trans fats. Moreover, a sodium intake of no more than 2,400 mg per day is recommended, with an alternative target being to reduce sodium take by 1,000 mg per day.

Specific additional recommendations for secondary prevention of CVD. Besides lipid control, blood pressure, antiplatelet, diabetes control, and lifestyle recommendations discussed earlier, guidelines for secondary prevention also include therapy with a beta blocker, renin angiotensin, and aldosterone system blockers, as well as annual influenza vaccination (Smith et al. 2011). Specific systems implemented in the hospital setting, such as pre-printed discharge instructions, reminders on charts (which can be automated in the case of electronic medical records systems) are key to ensure maximal adherence to recommended therapies for secondary prevention of CHD.

Conclusions

CVDs account for the greatest burden of morbidity and mortality worldwide, and both in developed and in developing countries. Key cardiovascular risk factors, including hypertension, cigarette smoking, high blood glucose, physical inactivity, obesity, and elevated cholesterol are (in that order) the top leading causes of death worldwide. It has been estimated that elimination of obesity, unhealthy diets, and physical inactivity could reduce up to 80% of heart disease, stroke, and diabetes (Roth et al. 2017).

In a recent Presidential Advisory (Smith et al. 2012) issued by the presidents of the World Heart Federation, European Society of Cardiology, AHA, and other leading cardiac societies, the call to reduce non-communicable deaths by 25% by the year 2025 was noted (of which nearly

half are due to CVD) and key global targets recommended for adoption were: (1) a 10% reduction in the prevalence of insufficient physical activity; (2) a 25% reduction in the prevalence of raised blood pressure; (3) a 30% reduction in salt/sodium intake with recommended goal of achieving <5 grams salt intake (2,000 mg sodium) per day; and (4) a 30% relative reduction in the prevalence of current tobacco smoking. Also receiving support was a reduction of saturated fat intake by 15%, halving the prevalence of obesity, reducing alcohol intake by 10%, reducing elevated cholesterol by 20%, increasing by 50% the number of eligible persons to receive drug therapy to prevent heart attacks and strokes, and increasing availability of basic technologies and generic essential medicines for prevention of CVD.

Concerted global efforts aimed at coordinating care for those with pre-existing CVD (secondary prevention), primary prevention, identifying persons with cardiovascular risk factors and getting them the necessary treatments, as well as primordial prevention aimed at prevention of obesity and other major risk factors in the first place, are critical for reducing the morbidity and mortality associated with CVDs.

8.2

Cancer epidemiology and public health

Paolo Boffetta, Zuo-Feng Zhang, and Carlo La Vecchia

Introduction to cancer epidemiology and public health

Classification of neoplasms is based on the International Classification of Diseases-Oncology, now in its third edition (Fritz et al. 2000), into topographical categories (according to the organ where the neoplasm arises) and morphological categories (according to the characteristics of the cells). In addition to localization and morphology, neoplasms, which are characterized by abnormal growth, can be classified according to genetic and molecular characteristics, clinical behaviour, and response to therapy.

Benign and malignant neoplasms

Benign neoplasms represent localized growths of tissue with predominantly normal characteristics: in many cases they cause minor symptoms and are amenable to surgical therapy. They can be fatal because of their clinical importance when they occur in organs in which compression is possible and surgery cannot be easily performed (mainly the brain), and when they produce hormones or other substances with a systemic effect (e.g. adrenaline (epinephrine) produced by phaeochromocytoma). Because relatively little is known about the distributions and causes of most benign neoplasms, they will not be further discussed in this chapter.

Malignant neoplasms are characterized by progressive growth of abnormal cells with structural and functional alterations with respect to the normal tissue. In some cases, the alterations can be so serious that it becomes difficult to identify the tissue of origin. A peculiarity of most malignant neoplasms is their ability to invade the nearby tissue, and to migrate and colonize other organs via blood and lymph vessel penetration

and transport. The presence, extension, and control of metastases are often the critical factors to determine the success of therapy and the survival of cancer patients.

Carcinogenesis

Increasingly, neoplasms are characterized at the molecular level according to phenotypic aspects (e.g. presence of receptors, expression of genes) and genetic alterations (e.g. inherited or acquired mutations in one or multiple genes).

The understanding of the molecular and cellular mechanisms of carcinogenesis has greatly advanced in recent years. According to a widely accepted model, normal cells have to acquire six characteristics to become fully malignant (Hanahan and Weinberg 2011). These include the ability to produce growth signals (several known oncogenes mimic growth signalling), the lack of sensitivity to antigrowth signals (the retinoblastoma [Rb] protein and its homologues play a key role in the ability of the cell to decide whether to proliferate, to be quiescent, or to enter into a post-mitotic state, based on external signalling), resistance towards programmed cell death or apoptosis (in many cases via inactivation of the p53 protein), immortalization (normal cells have a limited replication potential that is related to the length of the telomeres: in malignant cells, overexpression of telomerase circumvents it), stimulation of blood vessel production (by changing the balance of angiogenesis inducers and countervailing inhibitors), and ability to invade and metastasize.

The acquisition of these neoplastic characteristics typically occurs by alterations of relevant genes, but an inability to maintain genomic integrity (so-called genomic instability, which includes reduced ability to repair DNA damage) is an additional feature of malignant cells, as accumulation of random mutations in genes involved in all the functions just mentioned would be a too rare event for the development of cancer during the normal lifespan. Inflammation also fosters multiple hallmark functions, and consequently promotes carcinogenesis. A final point to consider is the heterogeneity of neoplastic genetic alterations: the acquisition of the different biological capabilities of the neoplastic cell can appear at different times, and the particular sequence in which capabilities are acquired can vary widely, even among the same type of malignant tumours. In addition,

neoplasms contain a repertoire of normal cells in their stroma, including immune cells, which contribute to create the tumour microenvironment.

Several inherited conditions carry a very high risk of one or several cancers. High-penetrance genes (or high-risk genes) have been identified through family-based and other linkage studies (Table 8.2.1). These conditions, however, are rare and explain only a small proportion of human cancers. Genetic factors, including a large number of low-penetrance variants, however, are likely to play an important role in interacting with non-genetic factors to determine individual cancer risk.

The long process of carcinogenesis justifies the efforts to develop and apply screening approaches for early detection and treatment of selected subclinical neoplasms in healthy individuals.

Table 8.2.1 Examples of high penetrance cancer predisposition genes

Gene	Syndrome	Main targets
RET	Multiple endocrine neoplasia 2	Medullary thyroid carcinoma, pheochromocytoma, parathyroid adenoma
MET	Familial papillary renal cancer syndrome	Papillary renal cancer
APC	Familial adenomatous polyposis	Colorectal cancer
VHL	von Hippel-Lindau syndrome	Clear-cell renal carcinoma, hemangioblastoma, retinal angioma, pheochromocytoma
WT1	Wilms' tumour syndrome	Bilateral Wilms' tumour
RB1	Hereditary retinoblastoma	Retinoblastoma
NF1	Neurofibromatosis 1	Neurofibroma, neurofibrosarcoma, optic glioma
NF2	Neurofibromatosis 2	Vestibular schwannoma, meningioma
p53	Li–Fraumeni syndrome	Sarcoma, leukaemia, breast, brain, lung, pancreas and skin cancers, others
p16/DCK4	Hereditary melanoma syndrome	Melanoma
PTCH	Nevoid basal cell carcinoma syndrome	Basal cell carcinoma
MEN1	Multiple endocrine syndrome 1	Tumours of parathyroids, gastrointestinal endocrine tissues and anterior pituitary
BRCA1	Hereditary breast-ovarian cancer syndrome	Breast, ovary, prostate, and colon cancer
BRCA2	Hereditary breast-ovarian cancer syndrome	Breast (also male) and ovary cancer
PTEN	Cowden syndrome	Hamartoma, breast, and thyroid cancer
hMSH2, hMLH1, hPMS1, hPMS2	Hereditary non-polyposis colon	Colon, endometrium, ovary, stomach cancers, others

Gene	Syndrome	Main targets
ATM	Ataxia-telangiectasia	Leukaemia, lymphoma, breast cancer
XP(A-G)	Xeroderma pigmentosum	Skin cancer
BLM	Bloom syndrome	Leukaemia, lymphoma, most cancers
FAC, FAA	Fanconi anaemia	Acute myeloid leukaemia, others
WRN	Werner syndrome	Sarcoma, melanoma, thyroid carcinoma

Cancer epidemiology and distribution

The development of cancer epidemiology has formed the basis for knowledge about the causes and the possible preventive strategies which has greatly advanced during the last several decades. The identification of the determinants of cancer relies on two complementary approaches, the epidemiological and the experimental.

Table 8.2.2 reports the lowest and highest country-specific incidence rates of selected cancers, as well as the 20th and the 80th percentiles of the respective rankings, as estimated in the Globocan 2018 project (Bray et al. 2018; Ferlay et al. 2019). For all cancers combined, the ratios of 80th percentile to the 20th percentile are 2.8 for men and 2.0 for women. In both sexes, the highest 80th/20th percentile ratio among common cancers was for lung cancer (8.8 in men, 6.2 in women). This comparison is based on stable figures, and indicates larger variations among very-high-risk and very-low-risk areas. The highest ratios in Table 8.2.2 represent extreme geographic differences that deserve epidemiological investigation into environmental and genetic factors in the development of cancer.

Table 8.2.2 Ratio of the 20th and 80th percentile in the ranking of country-specific estimated age-standardized incidence rates of selected cancers—Globocan 2018 (Bray et al. 2018)

Cancer	Men	Women
All cancers	2.8	2.0
Oral cavity, pharynx	4.5	2.7
Nasopharynx	32	13
Oesophagus	4.6	5.3
Stomach	3.7	2.7
Colon-rectum	5.0	3.7
Liver	3.0	2.5
Pancreas	4.8	5.0
Lung	8.8	6.2
Melanoma	8.1	15
Breast	–	2.6
Cervix	–	3.6
Endometrium	–	5.3
Ovary	–	2.1
Prostate	4.9	–
Bladder	6.4	4.0
Kidney	10	6.0
Nervous system	6.3	6.4
Non-Hodgkin’s lymphoma	2.7	2.9
Leukaemia	2.7	2.6

Analytical studies (case–control and cohort) have shown the causal role of specific exposures in the aetiology of several malignant neoplasms. One limitation of the epidemiological approach, which may prove of critical

importance in trying to detect comparatively small increases in risk, as in the case of environmental pollutants, is that even in the best conditions it is impossible to confidently identify by epidemiological means an increase in risk smaller than about 20% and serious problems arise in the interpretation of increases below 50%, as the biases inherent in any observational study are of at least this order of magnitude (Boffetta et al. 2015; Lagiou et al. 2018).

The identification of carcinogens via experimental studies relies on three types of tests: (i) long-term (often lifetime) carcinogenicity tests in experimental animals, most commonly rodents (mice, rats, and hamsters); (ii) short-term tests assessing the effects of chemical agents on a variety of end points belonging to three general classes: DNA damage, mutagenicity, and chromosome damage; and (iii) mechanistic tests, aimed at identifying the intermediate steps in the compound-specific carcinogenic process.

These tests are valuable to the extent that such effects may reflect underlying events in the carcinogenic process. Indeed, consistent positivity in tests measuring DNA damage, mutagenicity and chromosomal damage is usually regarded as indicating potential carcinogenicity of the tested agent. In addition, a number of factors, including inflammation (Mantovani et al. 2019), hormones and overweight/obesity, show carcinogenic effects through non-genotoxic pathways, for which mechanisms of carcinogenesis are less well defined and their biomarkers are sparse (Boffetta and Islami 2013).

Results of laboratory tests constitute useful supporting evidence when adequate epidemiological data for the carcinogenicity of an environmental agent exists, but they become all the more essential when the epidemiological evidence is non-existent or inadequate in quality or in quantity. In the latter case, although no universally accepted criteria exist to automatically translate data from long-term animal tests or short-term tests to cancer hazard in humans, an evaluation of the risk can be made on a judgemental basis using all available scientific evidence. This policy has been applied by the International Agency for Research on Cancer (IARC) in a systematic programme of evaluation of the carcinogenic risk of chemicals to humans. Agents are commonly classified in group 1 when the evidence of their carcinogenicity in humans, derived from epidemiological studies, is considered sufficient. They are classified in group 2A when the evidence in humans is limited and the agent is an experimental carcinogen and in group 2B when evidence of carcinogenicity in humans is limited and less than sufficient evidence of carcinogenicity in experimental animals (IARC 2018).

Since 1972, IARC has published 124 volumes presenting evaluations and re-evaluations for 1,014 chemical, physical, and biological agents and groups of agents, as well as mixtures and exposure circumstances, such as occupations. A total of 120 agents have been classified in group 1, 82 in group 2A, and 311 in group 2B, and 500 in group 3 (not classifiable as to its carcinogenicity to humans). The complete list of agents, with their evaluations can be found on the Monographs website (https://monographs.iarc.fr).

Temporal changes in incidence rates, particularly when they take place over a few decades, are incompatible with a genetic explanation. However, the possibility of environmental exposure changes as well as their possible interaction with genetic factors might contribute partially to temporal changes in incidence rates. Recorded incidence rates are also affected by changes in disease classification, diagnostic precision, and registration quality. Mortality rates are, in addition, affected by changes in treatment effectiveness. However, marked trends like the one for lung cancer mortality (Malvezzi et al. 2017) and other fatal neoplasms with poor prognosis are most likely to reflect real time trends in cancer rates, pointing to the importance of environmental factors.

Etiological risk factors of cancer

A number of non-genetic agents and exposures are associated with an increased risk of malignant neoplasms, but their importance varies in different population settings and for neoplasms from different organs.

Tobacco and related agents

Tobacco smoking is the single major cause of human cancer worldwide (IARC 2004; GBD 2017). Tobacco-related cancers include cancers of the lung, nasal cavity, larynx, oral cavity, pharynx, oesophagus, stomach, liver, pancreas, colorectum, ovary (mucinous histotype), uterine cervix, kidney, and bladder, as well as myeloid leukaemia. In high-income countries, tobacco smoking has been estimated to cause approximately 30% of all human cancers (Doll and Peto 2005), though—given smoking cessation in men—this proportion may tend to somewhat decline now. In many medium- and low-income countries, the burden of tobacco-related cancer is still

lower, given the relatively later start of the tobacco epidemics, which will result in a greater number of cancers in the future. All smoking tobacco products are carcinogenic, including cigarettes, cigars, cigarillos, pipe tobacco, waterpipe (hookah), bidi, and a large number of local products. Tobacco smoke contains a large number of carcinogens: the main groups are polycyclic aromatic hydrocarbons (PAHs), a group of compounds formed during the combustion of organic substances, and tobacco-specific nitrosamines, that are produced from nicotine during the curing of the tobacco leaf. Exposure to second-hand (passive) tobacco smoking is a risk factor for lung cancer (IARC 2004). An effect of second-hand smoking on other organs, such as nasopharynx, oral cavity, oesophagus, and larynx, is also suspected and plausible.

Use of smokeless tobacco products causes cancer of the oral cavity and other head and neck organs; an effect on other digestive organs is possible. The carcinogenicity of smokeless tobacco products appears to be due to their content in nitrosamines (Boffetta et al. 2008). Smokeless tobacco products represent a particularly important cause of cancer in South Asia, but they are widely used in other regions as well.

Areca nut is the main constituent of chewing products that contain a few slices of the nut wrapped in a betel leaf along with lime (calcium hydroxide), spices, and possibly tobacco. Chewing of areca nut, with or without tobacco, is a risk factor for cancer of the head and neck and the oesophagus (Mehrtash et al. 2017).

Opium, the dried latex obtained from the opium poppy contains two main groups of alkaloids: phenanthrenes such as morphine (10–16% of total weight) and codeine, which are the main psychoactive constituents, and isoquinolines, which have no central nervous system effects. The smoking of opium, which does not involve the burning of the agent but its heating, resulting in the vaporization of the active alkaloids, has been associated with increased risk of oesophageal and other digestive and respiratory cancers (Kamangar et al. 2014). Despite the fact that opium is illegal in almost all countries, smoking for recreational use remains prevalent in certain populations in West and Central Asia.

Diet and nutrition

Despite considerable research efforts in recent years, the exact role of dietary factors in causing or protecting against human cancer remains largely unquantified. There is sufficient evidence of an increased risk of liver cancer with exposure to aflatoxin, a contaminant produced by some fungi in some fungi in Southeast China, Taiwan, Southeast Asia, and sub-Saharan Africa. According to a recent comprehensive review on nutrition and cancer (Table 8.2.3) (WCRF/AIRC 2018), high intake of processed meat was considered to have convincing evidence for an increased risk of colorectal cancer, and high intake of red meat to probably increase the risk of the same cancer. High intake of food containing dietary fibres and whole grains probably decreases the risk of colorectal cancer, and that of non-starchy vegetables and fruits probably decreases the risk of cancer of upper aerodigestive tract.

Aflatoxin, a product of fungi of the *Aspergillus* genus, causes liver cancer in humans (Henry et al. 2002): contamination occurs when cereals and legumes are stored under hot and humid conditions. Exposure is widespread, but is particularly important in sub-Saharan Africa, Southeast Asia, and East Asia.

Table 8.2.3 Assessment of associations between dietary factors and human cancer (WCRF/AIRC, 2018)

Factor (high intake)	Oral cavity, pharynx, larynx	Oesophagus	Stomach	Colon, rectum	Lung	Breast	Prostate
Non-starchy vegetables or fruits	(–)	(–)					
Whole grains				(–)			
Foods containing dietary fibres				(–)			
Red meat				(+)			
Processed meat				+			
Dairy products				(–)			
Foods preserved by salt			(+)				

Direction of the effect: + increased risk; – decreased risk.

Strength of the evidence: no brackets: convincing evidence of an association.

Parentheses: probable association.

Intake of *Aristolochia sp.* results in exposure to aristolochic acid, a carcinogen of the upper urinary tract, including the renal pelvis (Matin et al. 2014). Exposure occurs via the use of these herbs in traditional herbal medicine, in particular in Asia, as well as contamination of other vegetables, such as wheat, as it was shown in the regions of Central Europe in which the so-called Balkan Endemic Nephropathy, another condition caused by exposure to aristolochic acid, was prevalent (Stiborová et al. 2016).

Alcohol drinking

Alcohol drinking is an established carcinogen, with no apparent safe dose. All types of alcoholic beverages cause cancer. The evidence is strongest for cancers of the oral cavity, pharynx, larynx, oesophagus, liver, pancreas,

colorectum, and female breast (WCRF/AIRC 2018). Globally, alcohol drinking was estimated to cause 7.2% of all cancers in men and 3.5% in women, for a total of 770,000 cases per year (Praud et al. 2016).

Coffee, tea, and maté drinking

Coffee drinking has been associated with a decrease in cancer risk: the evidence is strongest for liver and endometrial cancer, and it is suggestive for other cancers including colorectal and breast cancer, as well as melanoma (Alicandro et al. 2017). The mechanisms underlying such protective effect are not known, though possibly linked to favourable metabolic effects on glycemia, and non-causal explanations (e.g. better diet) cannot be excluded. The evidence linking tea drinking and cancer risk is inadequate: early reports of a possible protective effect of green tea have not been confirmed by subsequent research (Yi et al. 2019).

Drinking of maté, which is prevalent in some South American countries, has been associated with an increased risk of oesophageal cancer (Loria et al. 2009). Since maté is often drank at high temperature, this is probably due in part to a thermal effect, since also hot tea drinking at has been associated with oesophageal cancer risk (Chen et al. 2015).

Anthropometric characteristics

There is convincing evidence that adult body fatness is associated with increased risk of cancers of the oesophagus (adenocarcinoma), liver, pancreas, colorectum, breast (postmenopausal), endometrium, and kidney, and a causal association is probable for cancers of the head and neck, stomach, gallbladder, ovary and prostate (WCRF/AIRC 2018). Attained height is causally associated with risk of colorectal, breast, and ovarian cancer.

Physical activity

Regular vigorous workplace or recreational physical activity (e.g. at least 30 minutes per day) decreases the risk of colon cancer; a protective effect is also likely for breast and endometrial cancer (WCRF/AIRC 2018). The magnitude of risk reduction for colon and breast cancer is in the order of

40%, and a dose–response relationship has been shown for both neoplasms. Although regular physical activity contributes to weight control, the epidemiological evidence suggests that two factors also act independently. The mechanisms through which physical activity contributes to cancer prevention are not fully understood, but they may include enhancement of immune function, interference with sex steroids, and insulin and IGF-I pathways.

Infectious agents

As a whole, infectious agents represent the second most important risk factor for cancer worldwide. For 11 infectious agents (7 viruses, 1 bacterium, and 3 parasites) there is sufficient evidence that they cause cancer in humans (Table 8.2.4). Several others are suspected to cause cancer (Table 8.2.4). The proportion of total cancers attributable to infectious agents has been estimated to be 15.4% (Plummer et al. 2016); liver, stomach and cervical cancers are responsible for 86% of infection-related cancer. The burden of carcinogenic infections affects disproportionately low- and middle-income countries (23.4% of all cancers vs. 9.2% in high-income countries).

Table 8.2.4 Associations between infections and human cancer (Plummer et al. 2016)

Agent	Target organs*
Viruses	
Hepatitis B virus	Liver, bile duct (leukaemia/lymphoma)
Hepatitis C virus	Liver, bile duct, leukaemia/lymphoma
Hepatitis D virus	Liver
Human papilloma virus type 16	Cervix, vulva, vagina, penis, anus, oral cavity, tonsil, pharynx, (larynx)
Human papilloma virus type 18	Cervix, (oral cavity), (penis), (anus), (vulva)
Human papilloma virus types 31, 35, 39, 45, 51, 52, 56, 58, 59	Cervix
Human papilloma virus type 33	Cervix, (anus), (vulva)
Human papilloma virus types 6, 11	(Larynx)
Human papilloma virus types 26, 53, 66, 67, 68, 70, 73, 82	(Cervix)
Human papilloma virus types 30, 34, 69, 85, 97	
Human papilloma virus, genus-beta types (except 5 and 8) and gamma types	(Skin)
Human papillomavirus types 5, 8 (in patients with epidermodysplasia verruciformis)	(Skin)
Human immunodeficiency virus 1	Anus, Kaposi sarcoma, cervix, eye, leukaemia/lymphoma, (liver/bile duct), (skin), (vulva), (vagina), (penis)
Human immunodeficiency virus 2	Kaposi sarcoma, non-Hodgkin’s lymphoma
Human T-cell lymphotrophic virus I	Adult T-cell leukaemia/lymphoma
Human T-cell lymphotrophic virus II	
Epstein–Barr virus	Nasopharynx, leukaemia/lymphoma, (stomach)
Human herpes virus 8	(Kaposi’s sarcoma), leukaemia/lymphoma

Agent	Target organs*
Merkel cell polyomavirus	(Skin)
Bacteria	
Helicobacter pylori	Stomach, leukaemia/lymphoma
Parasites	
Schistosoma haematobium	Bladder
Schistosoma japonicum	(Colorectum, liver/bile duct)
Schistosoma mansoni	
Opistorchis viverrini	Liver/bile duct
Opistorchis felineus	
Clonorchis sinensis	Liver/bile duct
Malaria (*Plasmodium falciparum*)	(Leukaemia/lymphoma)

* suspected target organs in parentheses.

Occupation and pollution

While some occupational carcinogens (e.g. *bis*-chloro methylethers) represent today a historic curiosity, exposure is still widespread for carcinogens such as asbestos, crystalline silica and mixtures of PAHs (Table 8.2.5). Estimates of the burden of cancer attributable to established occupational carcinogens in high-income countries result in figures in the order of 3–5% in men and 0.5–2.5% in women (Boffetta et al. 2009; Brown et al. 2018; Islami et al. 2018). Estimates for low- and middle-income countries are uncertain because of lack of valid data on prevalence of exposure to occupational carcinogens.

Table 8.2.5 Occupational carcinogens (Boffetta et al. 2010)

Agents, mixture, circumstance	Main industry, use
Individual agents and groups of agents	
4-Aminobiphenyl	Pigment
Arsenic and arsenic compounds	Glass, metal, pesticide
Asbestos	Insulation, filter, textile
Benzene	Chemical, solvent
Benzidine, dyes metabolized to benzidine	Pigment
Benzo[a]pyrene	Combustion fumes
Beryllium and beryllium compounds	Aerospace
Bis(chloromethyl)ether and chloromethyl methyl ether*	Chemical intermediate
1,3 Butadiene	Plastics, rubber
Cadmium and cadmium compounds	Dye/pigment
Chromium[VI] compounds	Metal plating, dye/pigment
Dioxin	Chemical
Ethylene oxide	Sterilant
Formaldehyde	Plastics, textiles, laboratory agent
Mustard gas*	War gas
2-Naphthylamine	Pigment
Nickel compounds	Metallurgy, alloy, catalyst
PCB-126	Chemical
Plutonium-239 and its decay products	Nuclear industry
Radium-226 and its decay products*	Luminizing industry
Radium-228 and its decay products*	Luminizing industry
Radon-222 and its decay products	Mining
Silica, crystalline	Stone cutting, mining, glass

Agents, mixture, circumstance	Main industry, use
Solar radiation	Agriculture
Talc containing asbestiform fibres	Paper, paints
Trichloroethylene	Solvent, dry cleaning, metal
Vinyl chloride	Plastics
X- and γ-radiation	Medical
Mixtures	
Coal-tar pitches	Construction, electrode
Coal-tars	Fuel, construction, chemical
Diesel engine exhaust	Transport
Leather dust	Leather
Mineral oils, untreated	Metal
Shale-oils	Fuel
Soot	Pigment
Wood dust	Wood
Exposure circumstances	
Aluminium production	
Auramine, manufacture of	Pigment
Boot and shoe manufacture and repair	
Coal gasification	
Coal-tar distillation	
Coke production	
Haematite mining (underground) with exposure to radon	
Iron and steel founding	
Magenta production*	Pigment
Painter (occupational exposure as a)	
Rubber industry	

Agents, mixture, circumstance	Main industry, use
Strong inorganic-acid mists containing sulphuric acid	Metallurgy

* Agent mainly of historical interest.

Air and water pollution

High level of indoor and outdoor air pollution can cause lung cancer: the evidence is strong for non-smoking women experiencing high level of fumes from cooking and heating in poorly ventilated households: studies have mainly been conducted in Asia (Bruce et al. 2015). Air pollution may contain lung carcinogens such as PAHs, and has been linked to an increased risk of lung cancer, although the quantification of the risk is problematic. Estimates of the burden of cancer due to outdoor air pollution are uncertain, but typically below 1% (Boffetta et al. 2015; Brown et al. 2018; Islami et al. 2018).

Contamination of drinking water by high level of arsenic, primarily from natural sources, has been causally associated with an increased risk of cancers of the lung and bladder, and possibly other organs such as skin and kidney in studies conducted in highly contaminated areas of South America, South Asia, and East Asia (Karagas et al. 2015). No apparent effect was shown at low concentrations (below 100 µg/L), which are prevalent is most regions of the world. Chlorination of drinking water results in low-level formation of chloroform and related compounds, called trihalomethanes, which are carcinogenic in experimental systems (Richardson et al. 2007). An increased risk of bladder cancer from consumption of chlorinated water has been suggested, but the evidence is not conclusive (Hrudey et al. 2015). Contamination of drinking water by microcystins has been associated to excess risk of liver and colorectal cancer, but the evidence is inconclusive (Martínez Hernández et al. 2009).

Ionizing and non-ionizing radiation

The estimates of the contribution of ionizing radiation to human cancer in high-income countries are on the order of 2–4% (Brown et al. 2018; Doll and Peto 2005). Several neoplasms, in particular acute lymphocytic leukaemia, acute and chronic myeloid leukaemia, and cancers of the breast,

lung, bone, brain, and thyroid are produced as a result of high-level exposure to ionizing radiation (IARC 2000). Ultraviolet (UV) non-ionizing radiation concerns exposure to solar radiation and artificial sources of UV radiation for cosmetic and medical purposes. Skin cancer, both melanoma and non-melanoma, results from exposure to UV radiation (Narayanan et al. 2010). Between 1 and 4% of all cancers are attributed to UV exposure in high-income countries (Boffetta et al. 2009; Brown et al. 2018), depending on the estimates of prevalence of exposure, besides the skin characteristics of different racial and ethnic groups.

Reproductive factors

The epidemiological evidence of a carcinogenic effect of reproductive factors is strongest for breast cancer: early age at menarche, low parity, late age at first pregnancy, and late age at menopause are all associated with an increased risk, while spontaneous and induced abortions are not (Tamimi et al. 2018). In addition, breastfeeding protects from breast cancer, with a stronger effect for cancers that are negative for hormone receptors (Islami et al. 2015). Apart from age at first pregnancy, the same reproductive factors seem to exert an effect on endometrial and ovarian cancer risk similar to that played on breast cancer, while the evidence of an effect on other cancers is inadequate. Estimates of the contribution of reproductive factors to the global burden of cancer differ greatly (from 1% to 15%), depending on the underlying assumptions, especially on the choice of the reference population (Boffetta et al. 2009; Doll and Peto 2005; Brown et al. 2018; Islami et al. 2018).

Hormones

Increased levels of endogenous oestrogens, prevalent in overweight postmenopausal women, are associated with an increased risk of breast and endometrial cancers, and a similar effect is likely to be played by endogenous androgens (Crous-Bou et al. 2018; Tamini et al. 2018). The role of other hormones, such as progesterone and prolactin, in these cancers is not clearly known, nor is the role of endogenous androgens in prostate cancer.

There is a large body of evidence that growth hormones, in particular, insulin and IGF-I, have a strong effect on the risk of breast, colon, pancreas, endometrium, prostate, and possibly other cancers (Faulds et al. 2012). An effect of other endogenous hormones such as growth hormone on cancer risk is plausible but not fully elucidated in epidemiological studies (Clayton et al. 2011).

There is also strong evidence supporting an increase in cancer risk following exposure to exogenous hormones. Current and recent (up to 10 years) use of oral contraceptives entails a small increase in breast cancer risk, but no excess risk is apparent 10 or more years after cessation of use (CGHFBC 1996). Long-term use of oral contraceptives is associated with an increased risk of liver cancer, while the risk of endometrial and ovarian cancer is decreased following oral contraceptive use (Cibula et al. 2010). Postmenopausal hormonal therapy increases the risk of breast and endometrial cancer (CGHFBC 1997). In the case of breast cancer, the effect is stronger for combined oestrogen–progestogen combinations than for other types of hormonal therapy (Beral et al. 2003). The evidence for other organs is inconclusive. Tamoxifen is widely used for treatment of breast cancer: beyond its therapeutic effects, it decreases the risk of contralateral breast cancer, but it increases the risk of endometrial cancer (Crous-Bou et al. 2018; Tamini et al. 2018). Studies of transgender men and women might also be indicative of potential impact of sex hormones in the development of cancer. Because of relatively large dosage of sex hormone therapy for transgender individuals, the risk of cancer would increase and the latency might be much shorter than other hormonal factors (de Blok et al. 2019).

Perinatal factors

High birth weight is possibly linked with an increased risk of premenopausal breast cancer (WCRF/AIRC 2018). In general, perinatal factors have been proposed to cause a sizeable proportion of human cancers, but the estimate is subject to uncertainty. The implications of these findings for preventive strategies will be clarified by a more detailed understanding of the underlying carcinogenic mechanisms (Xue and Michels 2007).

Medical procedures and drugs

In addition to postmenopausal hormonal therapy, oral contraceptives, and tamoxifen, other drugs may cause cancer. Many cancer chemotherapy drugs are active on the DNA, in order to block the replication of cancer cells. This, however, might result in damage to normal cells, including cancer transformation. The main neoplasm associated with chemotherapy treatment is leukaemia, although the risk of solid tumours is also increased. A second group of carcinogenic drugs includes immunosuppressive agents, which have been studied in particular in transplanted patients (Gutierrez-Dalmau and Campistol 2007). Non-Hodgkin lymphoma and leukaemia are the main neoplasms caused by these drugs. Phenacetin-containing analgesics increase the risk of cancer of the renal pelvis (Piper et al. 1985).

There is strong evidence from observational studies that aspirin reduces the risk of colorectal cancer (Cuzick et al. 2015), an effect probably shared by other non-steroidal anti-inflammatory drugs. No precise estimates are available for the global contribution of drug use to human cancer. It is unlikely, however, that drugs represent more than 1% in high-income countries (Doll and Peto 2005). Furthermore, the benefits of such therapies are usually much greater than the potential cancer risk.

Use of ionizing radiation for diagnostic purposes is likely to carry a small risk of cancer, which has been demonstrated only for childhood leukaemia following intrauterine exposure (IARC 2000). Computed tomography (CT) scan in children may also increase subsequent cancer risk (Pearce et al. 2012). Radiotherapy increases the risk of cancer in the irradiated organs. There is no clear evidence of an increased cancer risk following other medical procedures, including surgical implants.

Medical conditions

Changes in immunological function are likely to play an important role in human cancer, but epidemiological studies have been largely unable to identify specific factors determining an increased or a decreased risk. Both severe immunosuppression and immunostimulation are associated with an elevated risk of cancer (Engels and Hildesheim 2018). Individuals infected with the human immunodeficiency virus (HIV) and patients undergoing immunosuppressive treatments, such as transplant recipients, are at increased risk of non-Hodgkin lymphoma, Kaposi sarcoma, skin cancer, and infectious-related cancers such as cervical cancer (Zucchetto et al. 2016;

Engels and Hildesheim 2018). In addition, patients suffering from systemic autoimmune diseases are also at increased risk of lymphoma and possibly other neoplasms (Engels and Hildesheim 2018). The significance of less severe disturbances of the immunological competence is poorly known.

Several chronic inflammatory conditions represent a risk factor for cancer: the epidemiological evidence is particularly strong in the case of colorectal cancer following inflammatory bowel disease and of lymphoma following chronic infectious diseases such as tuberculosis, malaria, and herpes zoster. In addition, gastroesophageal reflux is an important cause of adenocarcinoma of the lower oesophagus, a neoplasm whose incidence is increasing in many regions (Abnet et al. 2018), and tuberculosis is a risk factor for lung cancer (Malhotra et al. 2016).

The global burden of neoplasms

The number of new cases of cancer which occurred worldwide in 2018 has been estimated at 18.1 million, of which 9.5 million among men and 8.6 million among women (Bray et al. 2018). The corresponding figure for cancer deaths was 9.6 million (5.4 million in men, 4.2 million in women). Lung, colorectal, stomach, liver, and breast cancer are the most common causes of cancer death and together they comprise half of the total burden; among men, lung, liver, stomach, colorectal, and prostate cancer are the most common causes of cancer deaths, while breast, lung, colorectal, cervix uteri, and stomach cancer are the most common causes of cancer deaths among women.

One complementary approach in assessing the global burden of neoplasms is to weigh the years of life with disability and add them to the years lost because of premature death (disability-adjusted life-years, DALYs). According to the Global Burden of Disease Study, cancer was responsible for 213.2 million DALY in 2016, of which 98% was due to premature deaths and 2% from living with disabilities (GBD 2018).

Distribution, aetiology, and prevention of selected cancers

The following paragraphs discuss the epidemiology of the 10 most common cancers; they are ordered based on numbers of estimated deaths based on

Globocan 2018 (Bray et al. 2018).

Lung cancer

In 2018 lung cancer was the most frequent cancer in the world as there were 2,093,876 new lung cancer cases, accounting for approximately 11.6% of the global cancer burden (Bray et al. 2018; Malhotra et al. 2018). Lung cancer was also the most common cause of cancer death, causing 1,761,007 deaths (18.4% of the total) in 2018.

Incidence and mortality rates for lung cancer are approximately twice as high among men as among women. Lung cancer is the most common cancer in men worldwide (14.5% of cases, 22% of deaths), with the highest age-standardized incidence rates observed in Micronesia/Polynesia (52.2/100,000) and Eastern Europe (49.3/100,000)) (Bray et al. 2018). The geographic pattern of incidence rates among women is slightly different, and generally lower, reflecting historic tobacco consumption patterns. The highest age-standardized incidence rates for women are observed in North America (30.7/100,000) and Northern Europe (26.9/100,000). The geographical patterns in mortality closely follow those in incidence due to the high fatality and relative lack of variability in survival in different regions of the world.

The main histological types of lung cancer include squamous cell carcinoma, small cell carcinoma, adenocarcinoma, and large cell carcinoma; the last decades have witnessed a decrease in the predominant squamous cell carcinoma type and an increase in adenocarcinomas.

The geographical and temporal patterns of lung cancer incidence are to a large extent determined by consumption of tobacco one or two decades earlier. A carcinogenic effect of tobacco smoke on the lung was demonstrated in the 1950s and has been recognized by public health and regulatory authorities since the mid-1960s (IARC 2004). The risk of lung cancer among smokers relative to the risk among never-smokers is on the order of over 20- to 40-fold. As compared to continuous smokers, the excess risk levels off in ex-smokers after quitting, but a residual excess risk is likely to persist in long-term quitters throughout life. An association has been shown in many studies between exposure to involuntary smoking and lung cancer risk in non-smokers. The magnitude of the excess risk among non-

smokers exposed to involuntary smoking is on the order of 20% (IARC 2004).

The UK Million Women Study demonstrated that the relative risks (RRs) of lung cancer were 10.5 for current smokers of ten cigarettes per day, 22.0 for 15, and 36.0 for 20 or more cigarettes per day (Pirie et al. 2013). Thus, even moderate smokers have substantial excess lung cancer mortality. This overall risk reflects the contribution of the different aspects of tobacco smoking: average consumption, duration of smoking, time since quitting, age at start, type of tobacco product, and inhalation pattern, with duration being the dominant factor.

The lifetime cumulative risk of lung cancer of a continuous smoker is 16% and it is reduced to 10%, 6%, 3%, and 2% among those who stopped at ages 60, 50, 40, and 30, respectively (Peto et al. 2000). In the United States, stopping smoking before the age of 40 years would reduce the risk of death associated with continued smoking by about 90% (Jha et al. 2013).

An increase in tobacco consumption is paralleled some decades later by an increase in the incidence of lung cancer; similarly, a decrease in consumption is followed by a decrease in incidence, as observed in the United States and other countries in which the tobacco epidemics has reached its maturity. A notable exception is China and other East Asian countries, with relatively high rates being recorded among women (21.9/100,000), probably due to very high prevalence of passive smoking and high levels of indoor air pollution.

The risk of lung cancer is increased among workers employed in several industries and occupations. For several of these high-risk workplaces, the agent (or agents) responsible for the increased risk have been identified. Of these, asbestos and combustion fumes comprising mixtures of PAHs are the most important. Occupational agents were responsible in the past for an estimated 5–10% of lung cancers in industrialized countries, though this proportion is likely to be smaller in recent years.

Pulmonary tuberculosis has demonstrated an increased risk to lung cancer, although it is not clear whether it is due to the chronic inflammatory status of the lung parenchyma or the specific action of the *Mycobacterium*. High levels of fibres and dusts might result in lung fibrosis (e.g. silicosis and asbestosis), along with chronic bronchitis and emphysema, conditions that also entail an increase in the risk of lung cancer.

Other concerns relate to the presence of urban air posing as a susceptible risk factor; however, the excess is unlikely to be larger than 20% in most polluted urban areas (Hamra et al. 2014).

There is conclusive evidence that exposure to ionizing radiation increases the risk of lung cancer (IARC 2000). Atomic bomb survivors and patients treated with radiotherapy for ankylosing spondylitis or breast cancer are at moderately increased risk of lung cancer, while studies of nuclear industry workers exposed to relatively low levels provided no evidence of an increased risk of lung cancer. Underground miners exposed to radioactive radon and its decay products, which emit α-particles, have been consistently found to be at increased risk of lung cancer (IARC 2001). The risk increased with estimated cumulative exposure and decreased with attained age and time since cessation of exposure (Lubin et al. 1994). Exposure to radon decay products mainly occurs in environmental setting (e.g. household exposure from soil).

Despite the large number of studies, no dietary factors have been conclusively linked to lung cancer risk. However, greater intake of green vegetable, fruits, food containing carotenoids, beta-carotene, retinol, isoflavones, and fibre are associated with suggested evidence of protective effects on lung cancer (WCRF/AICR 2018).

No high-risk genes for lung cancer have been identified, that can be of epidemiological and clinical importance. Genome-wide association studies (GWAS) with large sample size have identified polymorphisms of genes located within 15q25 (*CHRNA3* and *CHRNA5*), 5p15.33 (*TERT-CLPTM1L)*, and 6p21.33 (*BAT3*) to be associated with the risk of lung cancer. However, future studies are still needed to identify heritable risk factors and molecular pathways and signature of lung carcinogenesis (Marshall and Christiani 2013).

Prevention of lung cancer

Control of tobacco smoking (including involuntary smoking) remains the key strategy for the prevention of lung cancer. Reduction in exposure to occupational and environmental carcinogens (in particular indoor air pollution and radon), are additional preventive opportunities. There is strong evidence that low-dose CT chest scan may detect early lesions in high-risk

individuals (Moyer 2014); the benefit on mortality is estimated to be around 20% reduction (Rota et al. 2019).

Colorectal cancer

Cancers of the colon and rectum accounted in 2018 for an estimated 1,849,518 new cases and 880,792 deaths worldwide (Bray et al. 2018; Keum et al. 2018). They represent the third most frequent malignant disease in terms of incidence (10% of the total) and the second for mortality (9%). Colorectal cancer is the third most common cancer in men (10.9% of the total) and the second most common cancer in women (9.5% of the total).

The majority of cases of colorectal cancer occur in high-income regions of the world, but the incidence is rapidly increasing in countries in social and economic transition, in particular in Asia; geographical patterns are similar in men and women. Generally, rates are slightly higher among men than women. The highest age-standardized rates are observed in Northern and Central Europe (up to 70/100,000 for men and 40/100,000 for women), followed by Australia, Argentina, and North America. There is considerable geographical variation in incidence of colorectal cancer, and the lowest rates in the world are observed in South Asia and Western Africa (less than 5/100,000 for men and 3/100,000 for women) (Bray et al. 2018). A small increase in the incidence of colon cancer has been observed during the last few decades in most populations, but Western Europe over the last two decades (Siegel et al. 2014). Studies of migrant populations have shown that the risk of colon cancer approaches that of the country of adoption within one generation; the incidence is higher in urban than in rural populations.

The predominant histological type of malignant neoplasms of the colorectum is adenocarcinoma. This neoplasm is usually preceded by an adenomatous polyp, or adenoma, less frequently by a small area of flat mucosa exhibiting various grades of dysplasia. The malignant potential of an adenoma is increased by a surface diameter greater than 1 cm, by villous (rather than tubular) organization and by severe cellular dysplasia. Carriers of one adenoma larger than 1 cm have a two to four times increased risk of developing colon cancer; this risk is further doubled in carriers of multiple adenomas. On a topographical basis, the prevalence of adenomas detected during colonoscopy closely parallels the incidence of colon cancer.

Several studies have associated tobacco smoking with an increased risk of colorectal adenoma. For colon cancer, a modest increased risk following prolonged heavy smoking has been shown in some of the largest prospective studies (IARC 2004). High alcohol consumption (50 g alcohol/day) has been associated with moderately increased risk of colorectal cancer (Bagnardi et al. 2015).

Patients with ulcerative colitis and Crohn's disease are at increased risk of colorectal cancer. The overall RR has been estimated in the range of 5–20, and it is higher for young age at diagnosis, severity of the disease, and presence of dysplasia. The contribution of shared genetic and environmental factors in the genesis of the two inflammatory conditions and of colorectal cancer is not known. Diabetes and cholecystectomy have been associated with a moderate (1.5–2-fold) increased risk of (right-sided) colon cancer, possibly due to continuous secretion of bile. Patients with one cancer of the colon have a twofold risk to develop a second primary tumour in the colon or rectum, and the relative (though not the absolute) risk is greater for early age at first diagnosis (Levi et al. 2008). In women, an association has been shown also with cancers of the endometrium, ovary, and breast, possibly due to shared hormonal or dietary factors.

Several pathways which incorporate genetic instability (chromosomal instability (CIN) and microsatellite instability (MSI)), and inherited mutations of the adenomatous polyposis coli (*APC*) gene and mismatch repair genes pose as risk factors for colon cancer (Arends 2013). More than 100 susceptibility variants have been identified in multiple genetic regions through GWAs and sequencing studies (Huyghe et al. 2019). The majority of these studies were conducted in European descendants; however, studies in East Asian populations largely confirmed these genetic factors (Lu et al. 2019).

Several rare hereditary conditions are characterized by a very high incidence of colon cancer. Familial adenomatous polyposis, due to inherited or *de novo* mutation in the *APC* gene on chromosome 5, is characterized by a very high number of colonic adenomas and a cumulative incidence of colon or rectal cancer close to 100% by age 55. Gardner's syndrome, Turcot syndrome, and juvenile polyposis feature among the rarer diseases having this association. However, all these hereditary conditions, although very serious for the affected patients, account for no more than 1 per cent of colon cancers in the general population.

Lynch syndrome I, also known as hereditary non-polyposis colorectal cancer (HNPCC), is characterized by an increased risk of cancer of the proximal (right) colon, and is due to inherited mutation in one of two genes involved in DNA repair. Contrastingly, Lynch syndrome II has also an increased risk of extracolonic neoplasms, mainly of the endometrium and the ovary. Overall, hereditary non-polyposis colon cancer may account for a sizeable proportion of cases of colon cancer in Western populations. In addition to these hereditary conditions, first-degree relatives of colon cancer patients have a two- to threefold increased risk of developing a cancer of the colon or the rectum.

Overweight, obesity, and lack of physical activity are important risk factors of colorectal cancer (WCRF/AIRC 2018). The underlying mechanisms are not fully elucidated, but these factors may explain up to 20% of cases of the disease in high-income populations (Islami et al. 2018).

A large number of studies have been conducted to identify dietary factors other than alcohol associated with colorectal cancer. The evidence is strongest for the association between an increased risk and intake of processed meat. Less convincing associations have been reported for a protective effect of whole grains, dietary fibres, vegetables and fruit, dairy products and calcium, and for a carcinogenic effect of red meat intake.

Vitamin D, and in particular its most active form, 25(OH) D, has been inversely related to colorectal cancer risk (Giovannucci 2005). The preventive effect is only possible when the vitamin D receptor (VDR) is present so that the mechanisms to increase VDR expression would enhance the preventive ability of vitamin D (Stubbins et al. 2012). Reduction of the incidence of colorectal cancer is also associated with the increased use of aspirin and other non-steroidal anti-inflammatory drugs (Bosetti et al. 2012; Ferrández et al. 2012). Additionally, hormone therapy in menopause and other female hormones, including oral contraceptives (OC), have been inversely related to colon cancer risks, and hence may also play some protective role (ACS 2011a).

Prevention of colorectal cancer

Increased physical activity, avoidance of overweight and obesity, reduced alcohol drinking, and quitting smoking are the main tools for the primary prevention of colorectal cancer. While aspirin use could prevent colorectal

cancer as well, its use is not routinely recommended because of its spectrum of side effects.

Surveillance via flexible colonoscopy, involving removal of adenomas, is a secondary preventive measure. An additional approach consists in the detection of faecal occult blood. The method suffers from low specificity and, to a lesser extent, low sensitivity, in particular in the ability to detect adenomas. However, randomized trials have shown a reduced mortality from colorectal cancer after an annual test, although this is achieved at a high cost due to an elevated number of false positive cases, who must then undergo colonoscopy. Randomized trials have also demonstrated the efficacy of sigmoidoscopy in reducing colorectal cancer mortality, primarily for the distal colon.

Current guidelines recommend screening for average-risk individuals between ages 50 and 75 using colonoscopy (every 10 years), flexible sigmoidoscopy (every 5 years) or faecal occult blood test (FOBT, annually or biennially) (Benard et al. 2018; Wolf et al. 2018). However, there are disparities between recommendations issues by different national and international agencies.

Cancer of the stomach

Accounting for an estimated 1,033,701 new cases or 5.7% of the global cancer burden, stomach cancer is the sixth most frequent cancer in the world and the third most common cause of cancer death worldwide (782,685 deaths in 2012, 8.2%) in 2018 (Bray et al. 2018; Ye et al. 2018). This marks a substantive decrease in incidence since 1975 when stomach cancer was the most common neoplasm worldwide. Incidence rates are about twice as high in men as in women, with age-standardized rates highest (above 15/100,000 in men and 7/100,000 in women) in Eastern Asia, and Eastern Europe. Low-incidence areas include Africa, North America, and Northern Europe. The majority of cases occur in developing countries, with 44% of all new cases and almost 50% of deaths coming from China alone.

An increased risk of gastric cancer is associated with *Helicobacter pylori* infection. The biological plausibility of a causal association is also supported by a strong association between *H. pylori* and precancerous lesions, including chronic and atrophic gastritis and dysplasia. Given that the prevalence of infection is very high, especially in low- and middle-income

countries and among older cohorts, *H. pylori* can explain a large proportion of all cases of gastric cancer, or over 4% of all cancer cases globally (Plummer et al. 2016). However, only a small fraction of infected individuals are diagnosed as having stomach cancer. Persistent *H. pylori* infection due to a combination of virulence factors and immune subversion and manipulation mechanisms is associated with gastric carcinogenesis (Salama et al. 2013).

Another important cause of stomach cancer is tobacco smoking. Smokers have a 50–60% increased risk of stomach cancer, as compared to non-smokers. This relationship would indicate that smoking is responsible for approximately 10% of all cases (IARC 2004).

Throughout the world there is a consistent correlation between consumption of salt and salted foods and stomach cancer incidence. A large number of studies that have examined this relationship have generally found an increased risk of approximately twofold for frequent consumption of salt and salted foods. The relationship is biologically plausible, given that salt may lead to damage to the protective mucosal layer of the stomach.

A notably striking feature of gastric cancer is the dramatic decline in its incidence and mortality which has been observed in most high-income countries over the past century. The decline is apparent for both sexes. This continuous dramatic decline, as well as the results from migrant studies, suggests a strong environmental influence on the disease.

Reasons for the generalized decline in gastric cancer rates are complex and not completely understood. Almost certainly, these include a more varied and affluent diet and better food conservation, including refrigeration, as well as the effective treatment of *H. pylori* infection. Whether improved diagnosis and treatment have also played some role on the favourable trends in gastric cancer, particularly over most recent calendar periods, however, remains open to question.

A total of 11 variants were significantly associated with gastric cancer risk in a systematic review of GWAS: MUC1 rs2070803 at 1q22 (diffuse carcinoma subgroup), MTX1 rs2075570 at 1q22 (diffuse), prostate stem cell antigen (PSCA) rs2294008 at 8q24.2 (non-cardia), PRKAA1 rs13361707 5p13 (non-cardia), PLCE1 rs2274223 10q23 (cardia), TGFBR2 rs3087465 3p22 (Asian), PKLR rs3762272 1q22 (diffuse), PSCA rs2976392 (intestinal), GSTP1 rs1695 11q13 (Asian), CASP8 rs3834129 2q33 (mixed), and TNF rs1799724 6p21.3 (mixed) (Mocellin et al. 2015). The strongest

evidence is for variants of the *PSCA* gene, which have been identified in multiple populations, and may interact with H. pylori infection (Cai et al. 2017). These genes might regulate cell growth, differentiation, apoptosis, and angiogenesis and be associated with the development of stomach cancer.

Other intervention trials conducted in a Chinese population known to be micronutrient deficient observed that a combination supplement of beta-carotene, vitamin E and selenium did result in a small reduction in the risk of stomach cancer (Qiao et al. 2009), but recent findings on the issue on other, better nourished populations, are largely negative (Plummer et al. 2007).

Primary prevention of stomach cancer by dietary means is feasible by encouraging high-risk populations to decrease consumption of cured meats and salt preserved foods. Prevention may also be feasible through eradication of *H. pylori* infection, particularly in childhood and adolescence, and by avoiding mother to child transmission. Screening and early detection of stomach cancer have been developed in Japan and South Korea with the use of X-ray photofluorography to identify early lesions, followed by gastroscopy.

Cancer of the liver

The estimated worldwide number of new cases of liver cancer in 2018 is 841,080 (4.7% of the total), that of deaths is 781,631 (8.2%). More than 80% of the liver cancer burden is in middle and low-income countries (over 50% from China alone) (Bamia et al. 2018; Bray et al. 2018). Most low-income regions of the world, with the exception of South-Central and Western Asia, experience a high incidence of liver cancer. The highest rates (above 20/100,000 in men and above 6.5/100,000 in women) are recorded in Eastern and South-Eastern Asia, and Northern Africa. The lowest rates are in South-Central Asia, where age-standardized rates are below 5/100,000 in men and 2/100,000 in women. Intermediate rates (5–10/100,000 in men) are observed in areas of Southern Europe and North America. Rates are two- to threefold higher in men than women, and the difference is stronger in high-incidence than in low-incidence areas. The majority of liver cancers are hepatocellular carcinomas (HCC), which originates from hepatocytes; a second important type is cholangiocarcinoma, which originates from the biliary ducts.

Chronic infections with hepatitis B virus (HBV) and hepatitis C virus (HCV) are the main causes of HCC. The risk increases with early age at infection (in high-risk countries, most HBV infections occur perinatally or in early childhood), and the presence of cirrhosis is a pathogenic step. The estimated relative risk of developing HCC among infected subjects, compared to uninfected, ranged between 10 and 50 in different studies. On a global scale, over 75% of liver cancer cases are related to HBV and HCV infections, though their prevalence varies in different high-risk areas HCV infections, though their prevalence varies in different high-risk areas.

Ecological studies have shown that the incidence of HCC correlates not only with HBV and HCV infection, but also with contamination of foodstuffs with aflatoxins, a group of mycotoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, which cause liver cancer in many species of experimental animals (Turner et al. 2012). Contamination originates mainly from improper storage of cereals, peanuts, dried corns, and other vegetables and is prevalent in particular in Africa, South-East Asia, China, and Taiwan.

(Alcoholic) cirrhosis is probably the most important risk factor for HCC in populations with low prevalence of HBV and HCV infection and low exposure to aflatoxins, such as North America and northern Europe (La Vecchia 2007). The association between tobacco smoking and HCC is now established, with a RR of the order of 1.5 to 2 for tobacco smoking on liver carcinogenesis (IARC 2004).

Use of OC increases the risk of liver adenomas, and is associated with the risk of HCC, although the absolute risk is likely to be small. Case reports have associated use of anabolic steroids with development of liver cancer, but the evidence is not conclusive (Cibula et al. 2010).

Diabetes is also related to an excess risk of HCC, and the increased prevalence of overweight and obesity, and consequently of diabetes and non-alcoholic fatty liver disease (NAFLD), in several populations may have had some role in recent unfavourable trends of HCC in North America and other areas of the world. Combined exposure to overweight and diabetes led to a RR of HCC of 4.75, after allowance for hepatitis, alcohol, and other recognized possible confounding factors (Bosetti et al. 2014).

The excess risk of liver cancer associated with overweight/obesity and diabetes has been related to the development of NAFLD (Sanyal et al. 2010). NAFLD is characterized by excess fat accumulation in the liver, and ranges

from isolated hepatic steatosis to non-alcoholic steatohepatitis (NASH), the more aggressive form of fatty liver disease, which can progress to cirrhosis and HCC. However, NAFLD/NASH increases HCC risk even in the absence of cirrhosis (Bosetti et al. 2014).

Coffee drinking has been associated with a reduced risk of liver cancer, with a RR in the order of 0.66 (Bravi et al. 2017).

The incidence of cholangiocarcinoma is increasing in many regions of the world (Khan et al. 2019). In several areas of Southeast and East Asia cholangiocarcinoma is the main form of liver cancer and is linked to infection with the liver flukes, *Opistorchis viverrini* and *Chlonorchia sinensis*. Other risk factors of this type of cancer include primary sclerosing cholangitis, a rare inflammatory condition, as well as infection with HBV and HCV. A role of tobacco smoking, diabetes and overweight/obesity is suspected (Khan et al. 2019).

Prevention of liver cancer

In high-prevalence areas, HBV vaccination has to be introduced in the perinatal period. In the last few decades, many countries from Asia, Southern Europe, and, to a lesser extent, Africa have expanded their national childhood vaccination programme to include HBV. Reduction of the incidence of liver cancer in young adults was observed in Qidong, a high-risk area of liver cancer in China, because of both HBV vaccination and aflatoxin B_1 reduction in foods (Sun et al. 2013). A similar primary preventive approach is not available for HCV; however, new antiviral therapies have become available in recent years, which clear the infection and are expected to reduce the subsequent risk of liver cancer (Waziry et al. 2017).

Control of aflatoxin contamination of foodstuffs represents another important preventive measure. While this is easily achieved in high-income countries, its implementation is limited by economic and logistic factors in many high-prevalence regions. Control of alcohol drinking and tobacco smoking represent additional primary preventive measures.

Since about half of HCC, but not normal adult liver, secrete the fetal antigen α-fetoprotein, the detection of this marker has been proposed as a screening method. However, no population-based studies are currently available showing a decreased mortality from liver cancer in screened

populations. Approaches combining ultrasound and MRI are explored for early detection of liver cancer in high-risk individuals with cirrhosis.

Cancer of the breast

Breast cancer is the most important cause of cancer diagnosis and death among women, and accounted for an estimated 2,088,848 new cases and 626,679 deaths worldwide in 2018 (Bray et al. 2018; Tamini et al. 2018). The incidence of breast cancer is relatively low (less than 25/100,000) in most countries of Middle Africa, and some countries of East and South-Central Asia. The highest rates (70–100/100,000) are recorded in North America, Australia and New Zealand, Northern and Western Europe. The incidence of breast cancer has grown rapidly during the last few decades in many low-resource countries and slowly in high-income countries. In high-income countries, age-specific incidence rates increase sharply after age 45 and the rate in women aged 65+ is over 250/100,000. However, incidence rates in medium- and low-income countries are between 50 to 100/100,000 after age 45 (Fig. 8.2.1). Mortality rates remained fairly stable between 1960 and 1990 in most of Europe and the Americas; appreciable declines have occurred since the early 1990s. Incidence appears to increase linearly with age up to menopause, after which a further increase is less distinct (in high-income countries) or almost absent (in low-income countries). Women from high social class have consistently higher rates (about 30–50%) than women from low social class.

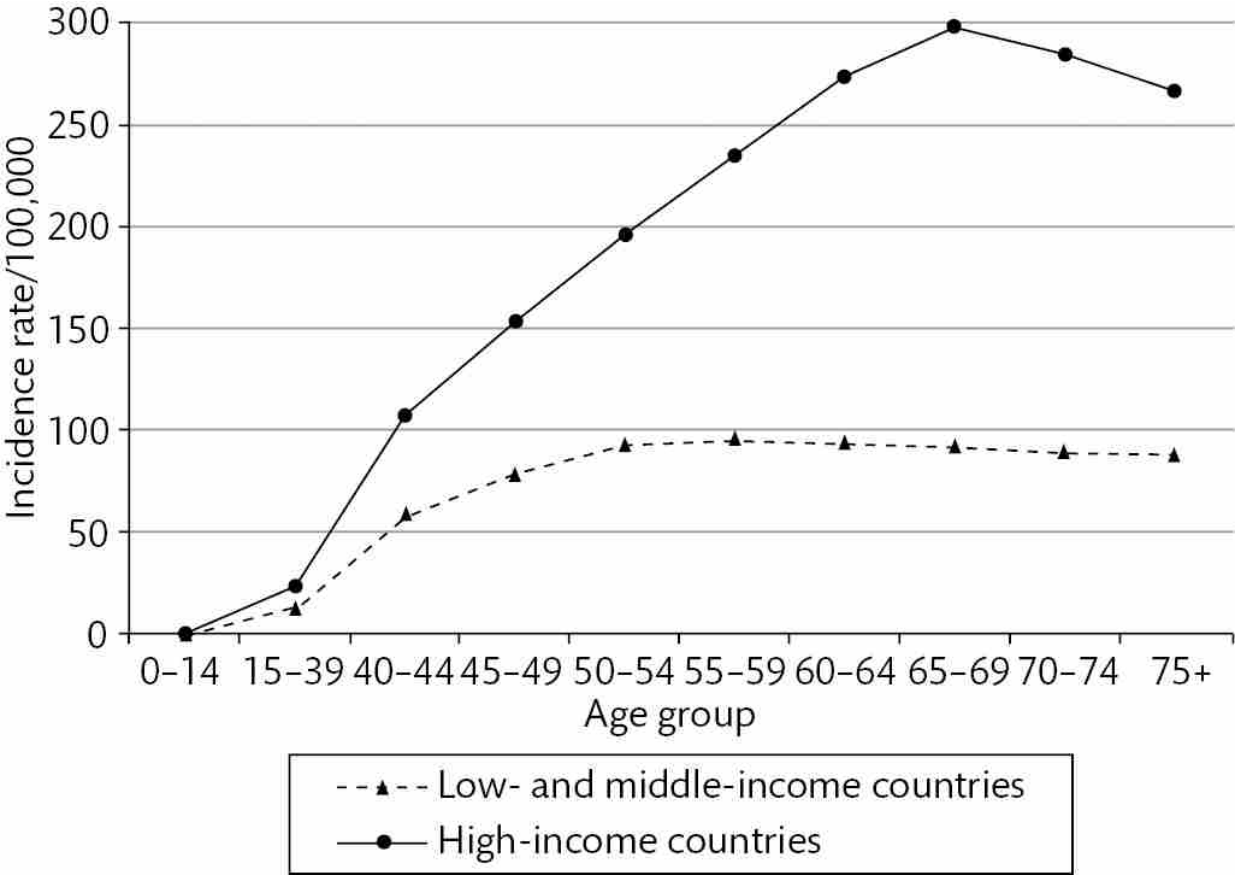

Fig. 8.2.1 Age-specific incidence of breast cancer by region of the world, 2012.
Source: data from Ferlay, J., et al. GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11, International Agency for Research on Cancer, Lyon, France, Copyright © IARC 2013, available from http://globocan.iarc.fr.

The combined evidence from reproductive factors points towards an important role for endogenous hormones in breast carcinogenesis. A direct assessment of the role of oestrogens and testosterone is also available from recent prospective studies collecting data from biological samples. Oestradiol concentrations in the blood have been directly associated with breast cancer risk in postmenopausal women, whereas data are fewer and results are less consistent in premenopausal women. The association might be stronger with oestrogen and progesterone receptor positive tumours. Comparable findings have been reported for measures of testosterone and other androgens, but the data are inconsistent for all endogenous hormones across major cohort studies.

Less than 1 per cent of all cases of breast cancer occur in men (Ruddy & Winer 2013). The incidence provides limited evidence of geographical and

interracial variations, with no clear correlation with incidence in women. Conditions involving high oestrogen levels, such as gonadal dysfunction, alcohol abuse, and obesity, are likely risk factors for breast cancer in men. *BRCA2* mutations are more frequent than *BRCA1* in male familial breast cancers.

Women suffering from the two most common benign breast diseases, fibrocystic disease and fibroadenoma, carry a two- to threefold increased risk of breast cancer. While these lesions are not likely to represent pre-neoplastic conditions, they share with breast cancer epithelial proliferation, linked to hormonal alterations.

A history of breast cancer in first-degree relatives is associated with a two- to threefold increased risk of the disease. Most of the role of familial history is likely to result from low-penetrance genes associated with hormonal metabolism and regulation, and DNA damage and repair. In the family linkage studies, breast cancer risk is greatly increased in carriers of mutations of several high-penetrance and low-frequency genes, including *BRCA1*, *BRCA2*, *PTEN*, and *TP53*. The mutations of these genes are associated with high risk of breast cancer, defined as inherited breast cancer syndrome. Although the cumulative lifetime risk in carriers of these genes is over 50%, they are rare in most populations and explain only a small fraction (2–5%) of total cases. There are exceptions, however, such as Ashkenazi Jews, among whom high-risk *BRCA1* or *BRCA2* mutations are responsible for an estimated 12% of breast cancers. In addition, a group of low penetrance and low-frequency DNA repair genes are related to moderate risk of breast cancer, including *CHEK2*, *ATM*, *BRIP*, and *PALB2*. Both high- and moderate-risk genes account for approximately 25% of cases with family history of breast cancer. A large number of GWAS have identified more than 100 susceptibility variants in genes involved in metabolism, apoptosis, cell cycle regulation, and mitochondrial regulation and other cancer-related functions (Low et al. 2018).

There are similarities and differences in risk profiles between triple negative (TNBC) and ER+ breast cancer based on results of the Women's Health Initiative study. Similar risk factors included body mass index (BMI), lack of physical activity, and breast density (Phipps et al. 2011a). Nulliparity was associated with decreased risk of TNBC but increased risk of ER+ breast cancer. Among parous women, the number of births was positively associated with TNBC and inversely associated with ER+ disease. Ages at

menarche and menopause were modestly associated with risk of ER+ but not TNBC (Phipps et al. 2011b). Tobacco smoking was not associated TNBC, but a risk factor for ER+ disease. Alcohol drinking is a risk factor specifically for ER+ breast cancer (Kabat et al. 2011).

Many lifestyle factors have been investigated as possible causes of breast cancer. Despite very extensive research, no dietary factors have been conclusively linked to risk of breast cancer (WCRF/AICR 2018). Alcohol drinking is an established etiological factor for breast cancer, in particular for the postmenopausal form of the disease (WCRF 2018). Consumption of three or more alcoholic drinks per day carries an increased risk on the order of 30–50%, with each daily drink accounting for about a 10% higher risk. Overweight, obesity, and adult weight gain are established risk factors of postmenopausal breast cancer, while the effect on the premenopausal form of the disease might go on the opposite direction (WCRF/AIRC 2018). It is likely that both overweight and heavy alcohol drinking act on breast cancer through mechanisms involving hormonal level or metabolism. Tobacco smoking has been inconsistently related to breast cancer, and risk quantification is not easy. A high level of physical activity, on the other hand, is likely to moderately decrease the risk (WCRF/AIRC 2018). Studies of occupational factors and of exposure to organochlorine pesticides have failed to provide evidence of an aetiological role (Salehi et al. 2008).

Survival from breast cancer has slowly increased in high-income countries, such as the United States, Canada, Sweden, Cuba, and Japan, where improvements in screening practices and treatments have achieved 5-year survival rates of 80–90%. In contrast, 5-year survival rates are between 60% and 79% in middle-income countries and below 60% in low-income countries (Coleman et al. 2008). In the United States, breast cancer survival in the black population is consistently poorer than the white population (Allemani et al. 2013).

Prevention of breast cancer

Primary prevention of breast cancer has been attempted via nutritional intervention, involving reduction of energy intake, reduction of the proportion of calories from fat, reduction of alcohol consumption, and increase in fruit and vegetable consumption. No evidence of efficacy has been produced so far. However, control of weight gain, particularly of

postmenopausal women, would have favourable implications in breast cancer risk.

The most suitable approach for breast cancer control is secondary prevention through mammography. The effectiveness of screening by mammography in women older than 50 years has been demonstrated, and programmes have been established in various countries, which however are not consistent among them (Jørgensen et al. 2017). The effectiveness in women younger than 50 is not yet demonstrated. Other screening techniques, including ultrasound or breast self-examination, have not been proven to reduce breast cancer mortality (Siu et al. 2016).

Cancer of the oesophagus

Approximately 572,000 new cases and 509,000 deaths of oesophageal cancer occurred worldwide in 2018 (Abnet et al. 2018; Bray et al. 2018). The geographical distribution of oesophageal cancer is characterized by very wide variations within relatively small areas. Very high rates (over 50/100,000) are recorded for both men and women in northern Iran, various provinces of eastern China, and certain areas of Central Asia (Torre et al. 2016). Intermediate rates in men (10–50/100,000) occur in South Africa, Eastern Africa, Eastern Asia, some provinces in China, and regions of Central Asia.

In all these high-risk areas, squamous cell carcinoma (SqCC) is the predominant histological type. Ethnic factors are suggested by the fact that populations at higher risk in Central Asia are of Turkish or Mongolian origin. Generally, rates in men are two- to fourfold higher than in women, although men and women have comparable rates in the very high-risk populations. In many high-risk areas, a decrease in the incidence of SqCC of the oesophagus has occurred during recent decades. In northern Europeans and white people in the United States, an increase in incidence was largely observed for adenocarcinoma of the lower oesophagus.

Tobacco smoking and alcohol drinking account for 90% or more of the cases of oesophageal SqCC in Western Europe and North America. However, this proportion is lower in low- and middle-income countries, particularly in selected high-risk areas of Asia and South America. In a large case–control study in China, both tobacco smoking and alcohol drinking accounted for only 40% of SqCC cases (Wu et al. 2011a).

The risk in heavy smokers relative to non-smokers is on the order of 5–10 in the Western populations. However, the RR estimate is much lower in the Asian populations. A recent large case–control study in Jiangsu, China reported that for individuals smoking more than 30 pack-years, the adjusted odds ratio (OR) was 1.85 (1.49–2.29) (Wu et al. 2011b). A strong relationship has been shown for the duration of smoking and average consumption. Quitting smoking substantially reduces the risk: the RR declines within 5 years after quitting, remains substantially elevated at least 10 years after cessation, and declines by 40% thereafter (Bosetti et al. 2006; Wu et al. 2011b). Thus, cessation of smoking could have an appreciable impact in reducing SqCC oesophageal cancer, and represents an obvious priority for prevention and public health purposes. Smoking black tobacco, high-tar, and hand-rolled cigarettes, as well as pipes, might exert a stronger effect than smoking other products. Chewing tobacco represents an important risk factor in India and southern Africa, but its role has not been confirmed in Central Asia. In the latter region, smoking and eating opium is a reason for the high incidence rates (Shakeri et al. 2012). Snuff use has also been related to an excess risk of oesophageal cancer, with RR of 3.5 for SqCC in a Swedish cohort study based on 10 non-smoking cases (Zendehdel et al. 2008; Lee 2011).

Areca nut chewing has been reported as an independent risk factor for SqCC in Asia and it may have additive interactions with tobacco smoking on the risk of the disease. Carcinogenic nitrosamines derived from areca nut are formed in the saliva of chewers and have been suggested as a risk factor for oral cancer and oesophageal cancer (Akhtar 2012).

In a meta-analysis of 40 case–control and 13 cohort studies, the pooled RRs for oesophageal SqCC were 1.38 for light drinking (<12.5 g/day), 2.62 for 12.5–50 g/day, and 5.54 for greater than 50 g/day. Among never-smokers, there was no association for light drinkers, but the RR rose to 3.1 for heavy drinkers (Bagnardi et al. 2015). The association with alcohol might be modified by genetic factors such as aldehyde dehydrogenase 2 (*ALDH2*) polymorphisms in Asian populations (Islami et al. 2011; Wu et al. 2013). It is unclear whether there are differences in the carcinogenic potency of different alcoholic beverages, but the most common beverage in each population is the most strongly related one. A reduction in the excess risk of oesophageal SqCC is suggested 15–20 years after quitting. Furthermore, the effect of alcohol is independent from the effect of tobacco, and the

interaction between the two exposures fits a multiplicative or additive model (Wu et al. 2011b).

Maté drinking has been associated with an increased risk of oesophageal cancer (Loria et al. 2009); hot tea drinking has also been associated with oesophageal cancer risk (Chen et al. 2015).

Familial aggregation of oesophageal cancer has been occasionally shown, with joint segregation of a gene responsible for *keratosis palmaris et plantaris* (tylosis). Studies of families without the tylosis gene have not provided evidence of an important role of other high-penetrance genetic susceptibility factors in oesophageal cancer. However, recent GWAS studies in Chinese and Japanese populations implicate certain low-penetrance genes in oesophageal cancer development. Reported genes encoded enzymes involved in the metabolism of alcohol or tobacco, DNA damage repair, and other carcinogenesis pathways (Cui et al. 2009; Wang et al. 2010; Wu et al. 2011).

Other active carcinogens might be mycotoxins or N-nitroso compounds. Mycotoxins, including fumonisin B1, have also been detected in mouldy corn from high-risk areas in China and southern Africa. In addition, in Japan, eating bracken fern has been associated with an elevated oesophageal cancer risk. The elucidation of dietary factors implicated in oesophageal carcinogenesis, in particular the possible role of mycotoxins and N-nitroso compounds (including endogenously formed nitrosamines), would represent an important step in the understanding and prevention of this disease. Oesophageal cancer is related to ionizing radiation, in particular in women irradiated for breast cancer.

Reduced intake of fresh fruits and vegetables also appears to represent a risk factor for oesophageal cancer. A similar effect has been suggested for low intake of fish, and high intake of red and processed meat. In general, a dietary pattern rich in foods from animal origin and poor in vitamins and fibre appears to increase oesophageal cancer risk (Bravi et al. 2012). The available data do not, however, allow us to establish the potentially preventive role of specific micronutrients from fruits and vegetables, and the results of most chemo-preventive trials with retinol, riboflavin, vitamin E, zinc, and selenium have failed to show a benefit.

Patients suffering from Plummer–Vinson syndrome, a sideropenic dysphagia due to deficit of iron, riboflavin, and other vitamins, had an increased incidence of hypopharyngeal and oesophageal cancers.

Oesophageal cancer risk is also increased among coeliac disease patients, possibly because of nutritional deficiencies. Subjects with a family history of oesophageal cancer have about threefold excess risk after adjustment for tobacco and alcohol, and the RR rose to over 100-fold in heavy drinkers and smokers with positive family history in first-degree relatives (Garavello et al. 2005).

Adenocarcinoma occurs in the lower third of the oesophagus. Its incidence has sharply increased in the last four decades in most Western countries and has largely affected white people. Barrett's oesophagus, a columnar metaplasia of the epithelium, is strongly associated with the subsequent development of adenocarcinoma. The main risk factor for Barrett's oesophagus and oesophageal adenocarcinoma is persistent reflux esophagitis. It is predominantly seen in countries such as the United States or Scotland.

Overweight, obesity, lack of physical activity, and gastroesophageal reflux are featured risk factors in adenocarcinoma. In a meta-analysis of 22 studies (Turati et al. 2013) compared with normal weight individuals, the pooled RR was 1.7 for overweight (BMI 25–30) and 2.3 for obese ones (BMI >30). The increased prevalence of overweight and inactivity in North America and northern Europe may partly or largely, explain the increased frequency of adenocarcinoma (La Vecchia et al. 2002; Buas and Vaughan 2013).

Tobacco smoking has also shown a consistent association with oesophageal adenocarcinoma. The pooled RR from a meta-analysis of 33 studies was 1.8 for ever smokers and 2.36 for current smokers (Tramacere et al. 2011; Buas and Vaughan 2013). In contrast, there is no material association between alcohol drinking and oesophageal adenocarcinoma (Tramacere et al. 2012). Epidemiological evidence suggests a protective role for high intake of fruits and vegetables and an unfavourable role for intake of salty food.

Prevention of oesophageal cancer

Avoidance of tobacco smoking and elevated alcohol drinking remains the main preventive approach in reducing the burden of oesophageal SqCC in Western populations. Improved diet, in particular increased consumption of fresh fruits and vegetables, might also contribute to prevention. Avoidance of tobacco, control of obesity, increased physical activity, and treatment of

reflux are considered the main issues for the prevention of oesophageal adenocarcinoma. Incomplete understanding of the role of other factors complicates the elaboration of preventive strategies in many high-risk regions, although decreasing intake of hot beverages and avoidance of tobacco and opium might be important (Wu et al. 2011a).

Cancer of the pancreas

The great majority of malignant neoplasms of the pancreas are adenocarcinomas which originate from the exocrine portion of the organ secreting digestive enzymes (Benetou et al. 2018). Rare pancreatic neoplasms include tumours (of uncertain clinical behaviour) of the endocrine portion, which secrete insulin and glucagon, as well as lymphomas and sarcomas.

Geographical and temporal variations exist in the sensitivity and specificity of clinical diagnosis and in the proportion of histological verification of pancreatic cancer cases. Even when comparing populations living in the same place at the same time (e.g. different social classes or age groups), differential access to healthcare might affect incidence and mortality data.

The disease accounts for an estimated 459,000 new cases in 2018, 48% of which (219,000) occurred in more developed regions (Bray et al. 2018) where the highest rates (close to 20/100,000 in men and 15/100,000 in women) are recorded among black people in the United States and European countries. The lowest rates, which may suffer from underdiagnosis, are recorded in South-Central Asia and Middle and Eastern Africa (below 2/100,000 in men and 1/100,000 in women). In the United States, the incidence ratio of black versus white people were 1.26 and 1.36 for men and women, respectively (ACS 2013).

The median of 5-year survival was 5.2 per cent with a range of 2.2–9.6% in countries with different economic status (ACS 2011b). From 2014 to 2018, the 5-year survival of pancreatic cancer has increased from 6 per cent to 9%, suggesting improvements in medical treatment (Rawla et al. 2019). However it remains on the most fatal cancers. Given its very poor survival, mortality rates closely parallel incidence rates. Rates are about 50% higher in men than in women. An increase in incidence and mortality has taken place since the 1970s, particularly in Europe, that can be attributed in part to

diagnostic improvements. However, incidence and mortality have levelled off and declined over recent years in men in the United States, Canada, and United Kingdom (Lucas et al. 2016).

Urban populations have higher rates than rural ones, but this may again reflect differences in quality of diagnosis. Migrant population studies suggest that first-generation migrants from low-to high-risk areas experience, after 15 or 20 years, rates that are even higher than those of the country of migration, suggesting an important role of environmental exposures occurring late in life (Benetou et al. 2018).

The best known risk factor for pancreatic cancer is tobacco smoking. The risk in smokers is two- to threefold higher than that in non-smokers, and a dose–response relationship and a favourable effect of quitting smoking have been shown in many populations. It has been estimated that 20–30% and 10% of cases in men and women are attributable to tobacco smoking (IARC 2004).

Interethnic differences in pancreatic cancer risk were evaluated in the Multiethnic Cohort. The RRs for pancreatic cancer were 1.60 (95% CI 1.30–1.98) for Native Hawaiians; 1.33 (95% CI 1.15–1.54) for Japanese Americans; 1.20 (95% CI 1.01–1.42) for African Americans when compared to European Americans (Huang et al. 2019). Some of these differences can be explained by differences in smoking habits.

Several medical conditions have been studied with respect to their associations with subsequent risk of pancreatic cancer. A history of pancreatitis increases the risk more than tenfold, with little difference between the alcoholic and non-alcoholic forms of the disease. An increased risk has also been shown in several studies of diabetic patients; the RR is likely to fall in the range of 1.3–2 and is higher in the short term after diagnosis of diabetes. Gastrectomy patients are at a two- to threefold increased risk of pancreatic cancer; the association does not appear to be confounded by tobacco smoking.

Studies have reported on the significant association between alcohol and pancreatic cancer; however, not all have addressed it. The current evidence indicates a weak effect of heavy alcohol drinking, but the evidence is not sufficient (Lucenteforte et al. 2012).

Nutritional and dietary factors have been suggested to be related to pancreatic cancer, including obesity and low physical activity, low intake of foods containing folate, red meat, and a low intake of vegetables and fruit

(WCRF/AICR 2018). The issue of nutrition, diet, and pancreatic cancer remains, however, largely undefined. Early reports of an association between coffee consumption and pancreatic cancer risk have not been confirmed by larger, more recent investigations, probably because of selection bias in the early studies (WCRF/AICR 2018).

A familial history of cancer of the pancreas is present in 8–10% of patients, suggesting a possible role for genetic factors. Specific hereditary conditions carrying an increased risk of pancreatic cancer include the Li–Fraumeni syndrome, hereditary non-polyposis colon cancer, and a group of rare hereditary pancreatitis that involve deficiency in enzyme metabolism: these conditions, however, explain only a small proportion of cases in the general population.

GWAS conducted on pancreatic cancer have identified more than 15 variants that are associated with susceptibility to the disease (Amundadottir 2016). These variants explain part of the familial aggregation of the disease (Childs et al. 2016).

There is no effective cure for pancreatic cancer, with the exception of surgery for a small number of patients. Screening methods are not available. Primary prevention is the only available tool for this disease: avoidance of smoking is the major practicable way for reducing the number of cases. Control of obesity and diabetes may be additional preventive measures.

Head and neck cancer (cancers of oral cavity, pharynx, and larynx)

Tumours of the oral cavity, oropharynx, hypopharynx, and larynx are grouped under the rubric of head and neck cancer because of shared histology (the majority are SqCC) and predominant aetiological factors (tobacco smoking and alcohol drinking). However, tumours of the lip, nasopharynx, and salivary glands have distinct aetiological factors. We will focus our discussion on cancers of the oral cavity, oropharynx, hypopharynx, and larynx in this section.

There were an estimated 706,000 new cases of cancers of the head and neck worldwide in 2018, of whom 355,000 are from the oral cavity, 177,000 from the larynx, and 174,000 from the oro- and hypopharynx. The estimated number of deaths was 358,000 (Bray et al. 2018).

Cancer of the oral cavity, oropharynx, and hypopharynx

The incidence of cancers of the oral cavity varies over 20-fold between high-risk areas (e.g. Papua New Guinea, Maldives, Sri Lanka, Pakistan, Bangladesh, and India) and low-risk areas (e.g. China, Vietnam, Korea, and Haiti) (Bray et al. 2018; Rider et al. 2018). In all populations, rates in the oral cavity and pharynx in men exceed those in women by a factor of 2–8. Incidence rates of both sites increased in Europe and the Americas until the late 1980s and have levelled off or declined in most countries over the last decade. When looking at subsites within the oral cavity and the pharynx, cancer of the oropharynx and hypopharynx account for as many or more cases than cancer of the oral cavity in high-risk European populations. Cancers of the tongue, floor of the mouth, and other parts of the oral cavity represent the majority of cases in India and the United States.

Tobacco and alcohol are the most important risk factors for cancer of the oral cavity and pharynx. In Western populations, smoking represents the main use of tobacco, and the RRs of oral cancer among smokers compared to non-smokers are on the order of 3–10. The risk is higher for heavy smokers, long-term smokers, and smokers of black tobacco or high-tar cigarettes. Cigar and pipe smoking also poses a risk, while stopping smoking is followed by a decrease in risk. In India, chewing tobacco is the main risk factor for oral cancer, although *bidi* and cigarette smoking also contribute to the risk. In the United States and Europe, use of smokeless tobacco has also been implicated in the development of oral cancer (Boffetta et al. 2008).

Consumption of alcoholic beverages increases the risk of oral and pharyngeal cancer (Islami et al. 2010; Tramacere et al. 2010; Turati et al. 2010). Relative to abstainers and light drinkers, the RR in heavy drinkers is on the order of 10. The effects of tobacco smoking and alcohol drinking are multiplicative or larger; that is, the effect of exposure to both is close to or greater than the product of their individual effects. The combined effect of tobacco smoking and alcohol drinking accounts for 80% of cancers of the oral cavity and pharynx in high-income countries. Similarly, tobacco chewing and smoking and their combination are responsible for a large proportion of these cancers in India.

With reference to alcohol drinking, additional issues are worth discussing. First, oral cancer risks show a clear decline after stopping smoking. The pattern of risk after stopping drinking remains unclear, though it appears that an appreciable excess risk persists for several years. Second, although

ethanol is the main carcinogenic ingredient in alcoholic beverages, it remains unclear whether different types of alcohol beverages have different influences on oral carcinogenesis. For example, some fruit-based spirits may be associated with higher risks than beer or wine (Boffetta and Hashibe 2006). This could explain some of the exceedingly high rates in countries like Hungary or Slovakia, where fruit-derived hard spirits are commonly consumed.

Human papilloma virus (HPV) DNA, detected in pre-neoplastic and neoplastic lesions of the oropharynx, is associated with over a 100-fold excess risk of oropharyngeal cancer (Pytynia et al. 2014). The association is less strong for cancer of the oral cavity and is suspected as an aetiological factor for cancer of the hypopharynx. The role of HPV in head and neck cancer has become increasingly important since the 1990s in Europe and North America, mainly because of changes in sexual practices, while it remains less important in other regions of the world. The role of other oral cancer risk factors, as well as diagnosis and disease management, is smaller than that of tobacco or alcohol, and remains largely undefined. For example, dietary and nutritional factors, such as fruit and vegetable consumption, have shown a protective effect on oral cancer risk. Moreover, earlier diagnosis and improved treatment on oral cancer survival may have favourably influenced oral cancer death rates over time.

Poor oral hygiene and ill-fitting dentures are likely additional risk factors for oral cancer. Several occupations have been sporadically reported to confer an increased risk of oral and pharyngeal cancer. The evidence is consistent only for employment as a waiter and/or bartender, probably reflecting an increased consumption of alcohol and exposure to environmental tobacco smoke (ETS).

The role of genetic susceptibility in oral carcinogenesis is probably modest. High-risk families have been reported only occasionally. However, a role is likely for low-penetrance factors, such as increased sensitivity to mutagens and genetic polymorphisms of enzymes implicated in the metabolism of alcohol (alcohol dehydrogenase and aldehyde dehydrogenase) (Lewis and Smith 2005). GWAS in Caucasian populations have identified five variants, including three variants located within the alcohol dehydrogenase genes (*ADH7*, *ADH1B*, and *ADH1C*), one 4q21 variant located near DNA repair genes *HEL308* and *FAM175A*, and one 12q24 variant located near the *ALDH2* gene to be associated with head and neck

cancer (Mckay et al. 2011). One GWAS with limited sample size conducted in an Indian population on chewing tobacco-related oral cancers did not identify any variant which reached genome-wide significance level (Bhatnagar et al. 2012). GWAS on head and neck cancer are relatively limited and replication studies in populations other than Caucasians are needed.

Prevention of oral and pharyngeal cancers

Avoidance of tobacco (smoking, chewing, and snuffing) and of excessive alcohol drinking represent the main preventive measures for cancers of the oral cavity and pharynx. Primary prevention through prophylactic HPV vaccination is promising and would involve both girls and boys (Kreimer 2014). It is unclear whether additional benefits might be obtained from an increase in fruit and vegetable intake and improvement of oral hygiene. Avoidance of excessive exposure to solar radiation would represent the main preventive approach for lip cancer. In populations at high risk of nasopharyngeal cancer from China and possibly other countries, avoidance of salted fish and other preserved food, in particular as weaning food, should be recommended.

Oral inspection aimed to identify pre-neoplastic lesions might be an effective approach for secondary prevention of oral cancer. The inspection can be performed by medically certified professionals, but also, in particular in high-risk areas from developing countries, such as India, by specifically trained health workers. A large-scale preventive trial demonstrated a reduction in oral cancer mortality during its 15-year follow-up, with larger reductions in smokers and drinkers and in those adhering to repeated rounds of screening (Sankaranarayanan et al. 2013).

Cancer of the larynx

More than 90% of cancers of the larynx are SqCCs; the majority originate from the supraglottic and glottic regions of the organs (Malhotra et al. 2018). The incidence in men is high (10/100,000 or more) in Cuba, Central Europe, and Central Asia, while the lowest rates (<1/100,000) are recorded in Africa. The incidence in women is ≤1/100,000 in most populations. In most high-income countries, rates have declined in men over the last two decades.

Up to 80% of cases of laryngeal cancer in high-income countries are attributable to tobacco smoking, alcohol drinking, and the interaction between the two factors (Malhotra et al. 2018). The effect of tobacco, with risks in smokers on the order of 10 relative to non-smokers, seems to be stronger for glottic than supraglottic neoplasms. Studies in several populations have shown a dose-response relationship and a beneficial effect of quitting smoking (Pelucchi et al. 2008). Smoking black-tobacco cigarettes confers a stronger risk than smoking blond-tobacco cigarettes. Studies from India have also reported an effect of chewing tobacco-containing products. The effect of alcohol is stronger for supraglottic tumours than for tumours at other sites. It is not clear, however, whether different alcoholic beverages exert a different carcinogenic effect.

There are suggestions of a protective effect exerted by a high intake of fruits and vegetables, although the evidence is not conclusive and the data regarding specific micronutrients, such as carotenoids and vitamin C, are inadequate. Data concerning a possible effect of other foods are not consistent.

Occupational exposure to asbestos and to mists of strong inorganic acids, in particular of sulphuric acid, are suspected causes of laryngeal cancer. A possible effect has been suggested for other occupational exposures, including nickel and ionizing radiation, but the evidence is not conclusive.

An etiological role of HPV infection in laryngeal cancer has been suggested. Laryngeal papillomatosis, a condition characterized by multiple benign papillomas caused by infection with HPV types 6 and 11, confers an increased risk of laryngeal cancer. A meta-analysis of studies assessing the presence of HPV-DNA reported strong associations between HPV infection and laryngeal SqCC, with a summary OR of 5.39 (95% confidence interval (CI) 3.25–8.94). A similar association was observed for HPV-16 (OR 6.07; 95% CI 3.44–10.70) (Li et al. 2013).

There is no evidence of strong genetic factors in laryngeal carcinogenesis. However, as for other head and neck cancers, polymorphisms for enzymes implicated in the metabolism of alcohol and tobacco and DNA repair might represent susceptibility factors (McKay et al. 2011).

Five-year survival rates are on the order of 65% in high-income countries and 40% in developing countries (Ellis et al. 2012). These patients are at very high risk of developing a second primary tumour in the oral cavity, pharynx, and lung. While shared risk factors are likely to play an important

role, it is plausible that host factors are also partially responsible. For example, an increased sensitivity to mutagens has been shown in lymphocytes of laryngeal cancer patients, in particular those with multiple tumours, as compared to controls. A report indicated that *p53*-related genes are related to susceptibility of second primary cancer in patients with primary head and neck cancer (Jin et al. 2013)

Control of tobacco smoking and excessive alcohol drinking, possibly together with an increased intake of fruits and vegetables, would prevent the majority of cases of laryngeal cancer in most populations. Control of exposure to known and suspected occupational carcinogens is an additional measure for exposed workers. Prophylactic HPV vaccination is promising (Kreimer 2014). No screening methods are currently available for laryngeal cancer.

Prostate cancer

Prostate cancer is the second most common cancer and the fifth leading cause of death from cancer in men worldwide with an estimated 1,276,000 newly diagnosed cases and 359,000 deaths in 2018 (Bray et al. 2018; Wilson and Mucci 2018). Almost 60% of the cases (754,000) occurred in high-income regions. It is the most common male malignant neoplasm in Oceania (79/100,000), North America (74/100,000), and Europe (62/100,000). The incidence is lower in low- and middle-income regions, such as Southern Asia (5.0/100,000). However, rates in Africa are relatively high (e.g. 32/100,000 in Western Africa), despite the low-income level of the region. Mortality rates of prostate cancer show less variability among regions, suggesting that the number of non-fatal cases diagnosed in different countries varies depending on screening and other diagnostic procedures.

The incidence of prostate cancer is highly dependent on the adoption of prostate-specific antigen (PSA) testing. Prostate cancer incidence has shown substantial changes following the introduction of PSA testing, with major increases due to the detection of large number of prevalent cases, followed by substantial declines. The changes in trends have been much smaller for mortality, but both in the United States and in Western Europe, peak rates were observed in the early 1990s, with a levelling off and a decline thereafter, approaching 20% in the EU (Bosetti et al. 2011).

The recent trends in prostate cancer mortality in high-income are consistent with a favourable impact of improved diagnosis, as well as of advances in therapy, on prostate cancer mortality in these countries (Hashim et al. 2016).

Prospective studies failed to provide convincing evidence of an increased risk linked to increased level of testosterone or other sexual hormones. An increased risk of prostate cancer was reported in retrospective studies following a history of benign prostatic hypertrophy, but no excess risk was found in prospective studies. If an association exists between prostatic hypertrophy and cancer, it can be due to shared aetiological factors or to a common pathological process.

It has been suggested that the risk of the disease increases with number of sexual partners and of encounters with prostitutes, and with a previous history of syphilis and gonorrhoea. Serological studies of HPV 16 and HPV 18 have shown an increased risk among positive subjects, but the findings are inconsistent. It is not clear at present, however, whether syphilis and HPV are causal factors or markers of infection with sexually transmitted agents, and hence general markers of inflammation.

A possible protective role of high intake of vegetables has been suggested in a few studies; high intake of meat, dairy products, total fat, and saturated fat might represent a risk factor. The evidence concerning other dietary factors, including fruit intake and intake of specific micronutrients, is, however, largely inconclusive at present. These include lycopene, a retinoid present in particular in tomatoes which has been found to be associated with a reduced risk in a few (but not other) studies, and calcium which has been associated with an elevated risk, possibly on account of its influence on vitamin D balance. There is, in fact, biological evidence that the most active form of vitamin D, 25(OH) D, has a favourable role on prostate cancer, but epidemiological data are inconsistent (Gilbert et al. 2011). Vitamin D may prevent prostate cancer progression, and hence the most aggressive forms of the disease (Li et al. 2007), and there is also an observation by a meta-analysis that an increased risk exists among individuals with elevated serum level of insulin-like growth factor 1 (Chen et al. 2009). An increased risk of the advanced prostate cancer has been reported among subjects with a high BMI (Discacciati et al. 2012). Overall, data on nutritional factors and prostate cancer are largely inconsistent (WCRF/AIRC 2018).

Carriers of *BRCA1* and *BRCA2* mutations have a four- to fivefold increased risk of prostate cancer with especially a two- to threefold increased risk of developing the same neoplasm in first-degree relatives. It is also similarly identified in small magnitudes in breast and colon cancers. More than 60 low-penetrance genetic variants entailing an increased risk of prostate cancer have been identified through GWAS (Rebbeck 2017), in particular within the 8q24 and possibly the 17q12 regions. The 8q24 region appears to be implicated in prostate cancer risk in all race/ethnic groups, while heterogeneity in other variants appear to explain some of the differences risk, in particular among people of African descent (Rebbeck 2017).

The wide geographical variability of prostate cancer suggests that environmental factors likely related to diet and other lifestyle factors, such as physical activity, are important determinants of the disease. Primary prevention, however, is hampered by the fragmentary knowledge of its precise causes. Secondary prevention has been proposed, based on measurement of PSA and digital rectal examination. There is little evidence from controlled trials that either procedure decreases the mortality from prostate cancer (Boyle and Brawley 2009; Welch and Albertsen 2009; Andriole et al. 2012; Schroder et al. 2012). Despite this lack of evidence, these procedures, in particular the PSA testing, have gained popularity in many countries, and are the cause of the steep increase in number of diagnosed cases since the mid-1980s in North America and other high-income countries. It is unclear how much of the decrease in mortality reported since the mid-1990s in the United States and in Western Europe can be attributed to a beneficial effect of (unplanned) use of PSA testing, but it is likely due mainly to improved management and treatment of the disease, including better surgery, radiotherapy, and medical therapy. In 2012, the United States Preventive Services Task Force (USPSTF) made a final recommendation against PSA based screening for healthy men because there is ‘moderate or high certainty that the service has no benefit or that the harms outweigh the benefits’ (Moyer 2012). The USPSTF issued a Grade D to discourage the use of the test by men of all ages for screening purpose. This recommendation is likely to have had an impact on recent trends in prostate cancer incidence (Fleshner et al. 2017).

Cancer of the uterine cervix

The estimated worldwide burden of cervical cancer in 2018 was approximately 570,000 new cases and 311,000 deaths (Bray et al. 2018; Sundström et al. 2018). On a global scale, cervical cancer is the fourth cause of cancer diagnosis and death in women; in particular, it is a major public health problem in middle- and low-income regions, where about 87% of cases (497,000, second most common cancer) and 91% of deaths (282,000, third most common cause of cancer death) occurred. Incidence rates are high (over 25/100,000) in sub-Saharan Africa and Melanesia. Rates are lowest (less than 7/100,000) in Western Asia and Northern Africa. Incidence and mortality rates have decreased steadily in high-income countries, but an upturn in incidence had been observed among young women in a few of these. Few data on temporal trends are available from middle- and low-income countries, but incidence has likely decreased during recent decades in those areas of the world, too. In high-income countries, rates increase up to age 60, while in middle- and low-income countries there is little increase above age 50. Cervical cancer hits preferentially women of lower education and social class.

Most invasive cancers are SqCCs or mixed adeno-squamous tumours. Chronic high-risk HPV infections regresses spontaneously in 60% of cases. Only about 15% of these patients develop, typically within 3–4 years, a cervical squamous intraepithelial neoplasia Grade 1 (CIN-1): this process is facilitated by cofactors such as cigarette smoking; immunosuppression; other cervical infections, such as chlamydia and herpes simplex virus, and oral contraceptive use. If left untreated, about 10% of CIN-1 patients progress to squamous intraepithelial neoplasia grades 2 and 3 (CIN2 and CIN 3). Overall, development of invasive cancer occurs in about 1% of women with high-risk HPV infection, and the required time-period is approximately 25–40 years (Basu et al. 2018).

Chronic infection with HPV is a necessary cause of cervical cancer. Using sensitive molecular techniques, virtually all tumours are positive for the HPV (Clifford et al. 2005). Different types of HPV exist, and those associated with cervical cancer are mainly types 16, 18, 31, 45, and 58 where HPV 16 is the main cervical carcinogen in most populations, while the distribution of other types varies by geographical region. The host response to HPV infection is important in determining its carcinogenic effect; immunosuppression, as present in transplanted patients and HIV

infected women, increases the risk of dysplasia, carcinoma *in situ*, and invasive neoplasms.

Sexual history of women (early age at first intercourse and increased number of sexual partners) and of their male partners (high number of sexual partners, presence of genital diseases, and contact with prostitutes) are risk factors for cervical cancer in many populations. They reflect an increased likelihood of HPV infection, as well as the duration of HPV infection. As for most carcinogens, in fact, duration of exposure is the major determinant of subsequent cancer risk (Plummer et al. 2016).

Tobacco smoking has also an independent effect on cervical carcinogenesis with a RR of 1.5–1.6 for current smokers, also once HPV infection is taken into account (IARC 2004; Moralejo 2009). A possible protective effect of a diet rich in fruits and vegetables has been suggested in a few studies, but the role of diet on cervical cancer risk is probably modest and largely undefined. Studies of infection with other agents, in particular *Chlamydia* and herpes simplex 2, have failed to provide consistent evidence of an effect independent from HPV. An increased risk, on the order of twofold, has been detected among long-term current or recent users of OC, which is not completely explained by sexual behaviour or HPV infection. However, there is no residual association 5–10 years after stopping OC use (La Vecchia and Bosetti 2003). Consequently, the public health implications of OC use on cervical cancer risk are limited in time (Cibula et al. 2010). Condom and (perhaps) diaphragm use, on the other hand, exert a protective effect, possibly via prevention of HPV infection.

Cytological examination of exfoliated cervical cells (the Papanicolaou smear, Pap test) is effective in identifying precursor lesions that can be removed, resulting in a substantial decrease in incidence of and mortality from invasive cancer. Cytological smears are not largely applicable, however, in countries with limited availability of cytologists and pathologists, including many countries with a high prevalence of HPV infection and high incidence of invasive cancer. Alternative approaches for secondary prevention have therefore been proposed, including visual inspection of the cervix with possible enhancement of precursor lesions by visual inspection with acetic acid (VIA). VIA performs as well as the Pap test in terms of sensitivity and specificity and can be used in low-income areas (Bradford and Goodman 2013). Use of HPV-DNA testing appears now, however, to be more specific and sensitive than the Pap test, and is,

therefore, likely to replace the Pap smear as the first screening method in the near future. The primary method for prevention of cervical cancer for future generations, however, is HPV vaccination. Prophylactic HPV vaccines have been progressively introduced worldwide since 2006, and large clinical trials and post-marketing studies have shown their effectiveness and safety against HPV-related lesions and CIN-1 (Lehtinen and Dillner 2013). Three vaccines are currently available (bivalent, quadrivalent, and non-avalent); they all contain antigens of HPV 16 and 18. More than 100 countries have introduced some vaccination programme; and an impact on HPV-related diseases is already visible in high-income countries that started vaccination earlier. Introduction of vaccines in low- and middle-income countries poses economic challenges, but would have a major impact on the cancer burden (de Sanjosé et al. 2019). In addition, smoking cessation may play a role since tobacco smoking is an independent aetiological factor of cervical cancer.

GWAS identified multiple loci within the major histocompatibility complex (MHC) region at 6p21.3 to be associated with cervical cancer, indicating the importance of impaired immune response in cervical cancer development (Chen and Gyllensten 2015).

Principles of primary and secondary cancer prevention

Primary prevention

Many determinants of malignant neoplasms, including UV radiation, ionizing radiation, tobacco smoking, alcohol drinking, overweight, a number of viruses and parasites, and a number of chemicals, industrial processes, and occupational exposures, are sufficiently well established to constitute logical priorities for preventive action. Two more reasons add weight to this priority: some of the agents are responsible for sizeable proportions of the cancers occurring today, and for many agents it is, in principle, feasible to reduce or even to completely eliminate exposure. If this is taken as the objective of preventive action, some practical points are helpful in guiding such action.

First, although epidemiological data in most cases do not allow a direct estimate of the risk of cancer at low doses, it is reasonable (at least from a preventive point of view) to assume that the dose (exposure)–risk relationships for agents acting through damage to DNA are linear with no

threshold (Peto et al. 1991). Second, the carcinogenic effect is not equally dependent on the dose rate (dose per unit of time) and on duration of exposure. For example, in regular smokers, the incidence rate of lung cancer depends more strongly on duration of exposure, increasing with the fourth power of it, than on dose rate, increasing only with the first or second power of it.

Furthermore, as illustrated earlier, the carcinogenic process may be represented as a succession of stages, taking place in the time span from first exposure to a carcinogenic agent to the appearance of clinical cancer. In its simplest form, as first brought out in mouse skin carcinogenesis experiments, the multistage process reduces to two stages: an irreversible 'initiation' stage inducing malignant cells, and a 'promotion' stage which propagates these cells into a malignant growth. A third stage of 'progression', characterized by an increased rate of growth and metastases, as well as an increase in chromosomal changes in the cell, has also been observed. Formal statistical multistage models of carcinogenesis have provided a useful framework to interpret on a common basis of (postulated) mechanisms both experimental and epidemiological observations. As the stages are assumed to occur in a specific sequence, some may be described as 'early' and some as 'late'. Epidemiological observations indicate that, for example, smoking has both an early stage effect, as indicated by the existence of a minimum interval of several years before an increase in risk of lung cancer becomes manifest, and a late stage effect, as indicated by the decrease in risk (with respect to continuous smokers) soon after stopping smoking.

Cancer prevention strategies have evolved from a predominant environmental and lifestyle approach to a model that matches individual-oriented actions with public health interventions. Advances in identifying, developing, and testing agents with the potential either to prevent cancer initiation, or to inhibit or reverse the progression of initiated lesions support this approach. Encouraging laboratory and epidemiological studies, along with studies of secondary end points using intermediate surrogate markers in prevention trials, have provided a scientific rationale for the hypothesis. Promising results have been reported for various types of cancer, in particular among high-risk individuals (Greenwald 2005; Dunn and Greenwald 2010).

Secondary and chemoprevention

Given the limitations still constraining the primary prevention of many cancers, early detection needs to be considered as a secondary and alternative option, based on the reasonable expectation that the earlier the diagnosis and the stage at which a malignancy is discovered, the better the prognosis if treated. This implies that an effective treatment for the disease exists and that the less advanced the cancer at the pre-clinical stage, the better the scope for treatment, and the better the prognosis. This latter aspect cannot be taken for granted.

Before a screening programme can be adopted on a large scale, a number of other requirements need to be fulfilled. First of all, a screening test (that is, a relatively simple and rapid test aimed at the presumptive identification of preclinical disease) must be available that is capable of correctly identifying cases and non-cases. In other words, both sensitivity and specificity should be high, approaching 100%. While high sensitivity is obviously important, given that the very purpose of screening is to pick up, if possible, all cases of a cancer in its detectable preclinical phase, it is specificity that plays a dominant role in the practical utilization of the test within a defined population. As the prevalence of a preclinical cancer to be screened in well-defined populations is often in the range of 1 to 10 per 1,000, if a test is used with a specificity of 95%, then 5% of results will be false positives. In other words, for every case which will turn out at the diagnostic work-up to be a true cancer (assuming 100% sensitivity), there will be 5–50 cases falsely identified as such and ultimately found not to be cancers. This situation is likely to prove unacceptable due to too high psychological and economic costs. One solution is an increase in specificity, for example, by developing better tests or combinations of tests, or by changing the criterion of positivity of a given test to make it more stringent (this necessarily decreases sensitivity). In addition, one might select populations with relatively high prevalence of the cancer (‘high-risk’ groups), so as to increase the number of the true positives. Whatever the group on which the programme operates, additional requirements are that the test is safe, less invasive, easily and rapidly applicable, and acceptable in a broad sense to the population to be examined. It has also to be cheap, but what is or is not cheap is better evaluated within a cost-effectiveness analysis of different ways of preventing a cancer case or death, an issue not further discussed here.

If these requirements are met, still nothing is known about the possible net benefit in outcome deriving from the screening programme (in fact, screening test plus diagnostic work-up plus treatment, as applied in a given population). To evaluate benefit, several measures of outcome can be assessed. An early one, useful but not sufficient, is the distribution by stage of the detected cancer cases which, if the programme is ultimately to be beneficial, should be shifted to earlier, less invasive stages of the disease in comparison with the distribution of the cases discovered through ordinary medical care. A second measure of outcome is the survival of cases detected at screening compared with the survival of cases detected through ordinary medical care. This is a superficially attractive but usually equivocal criterion, to the extent that screening may only advance the time of diagnosis (and therefore the apparent survival time), without postponing the time of death (‘lead-time bias’). A final outcome (and the main test of the programme) is the site-specific cancer mortality in the screened population compared with the mortality in the unscreened population.

Correct, unbiased comparison of this outcome, and thus unbiased measure of the effect of the screening programme, should in principle be made within the framework of a randomized controlled trial, in which two groups of subjects are randomly allocated to the screening programme and to no screening (that is, receiving only the existing medical care system) or to two alternative screening programmes, for instance, entailing different tests or different intervals between periodical examinations. However, largely due to pressures to adopt on a large-scale screening programmes hoped to be effective, a situation has often arisen where withholding screening to a group has been regarded as unethical or socially unacceptable, thus preventing the conduct of a proper experiment. Very few randomized trials evaluating the effectiveness of screening programmes are available. Comparisons are made through non-randomized experiments or through observational studies.

In addition to lead-time bias, three types of bias are peculiar to the assessment of screening programmes. Because of self-selection, persons who elect to receive early detection may be different from those who do not: for instance, they may belong to better educated classes, be generally healthier and health conscious, and this could produce a longer survival independent of any effect of early detection. In addition, cancers with longer preclinical phases, which may mean less biological aggressiveness and better prognosis, are, in any case, more likely to be intercepted by a programme of periodic

screening than cancers with a short preclinical phase, and a rapid, aggressive clinical course (length bias). Finally, because of criteria of positivity adopted to maximize yield of early cases, a number of lesions which in fact would never become malignant growths are included as ‘cases’, thus falsely improving the survival statistics (overdiagnosis bias) (Croswell et al. 2010).

Chemoprevention can also be considered for primary and secondary prevention of cancer, but data are negative or inconsistent for most micronutrients or other substances considered.

Conclusions

Neoplasms are a group of diverse diseases with complex distributions in human populations and with different etiological factors. Current knowledge of the causes of human neoplasms and the development of control strategies have led to the elaboration of lists of recommendations for their prevention (Table 8.2.6). A comprehensive strategy for cancer control might lead to the avoidance of a sizeable proportion of human cancers, and the greatest benefit can be achieved via tobacco control. However, such a strategy would imply major cultural, societal, and economic changes. More modest objectives for cancer prevention should focus on the neoplasms and the exposures that are prevalent in any given population. For example, vaccination of children against HBV is likely to be the most cost-effective cancer prevention action in many countries of Africa and Asia.

Table 8.2.6 European Code Against Cancer, fourth edition (Schüz et al. 2015)

1.	Do not smoke. Do not use any form of tobacco
2.	Make your home smoke-free. Support smoke-free policies in your workplace
3.	Take action to be a healthy body weight
4.	Be physically active in everyday life. Limit the time you spend sitting
5.	Have a healthy diet: • Eat plenty of whole grains, pulses, vegetables, and fruits • Limit high-calorie foods (foods high in sugar or fat) and avoid sugary drinks • Avoid processed meat; limit red meat and foods high in salt
6.	If you drink alcohol of any type, limit your intake. Not drinking alcohol is better for cancer prevention
7.	Avoid too much sun, especially for children. Use sun protection. Do not use sunbeds
8.	In the workplace, protect yourself against cancer-causing substances by following health and safety instructions
9.	Find out if you are exposed to radiation from naturally high radon levels in your home; take action to reduce high radon levels
10.	For women: • Breastfeeding reduces the mother's cancer risk. If you can, breastfeed your baby • Hormone replacement therapy (HRT) increases the risk of certain cancers. Limit use of HRT
11.	Ensure your children take part in vaccination programmes for: • Hepatitis B (for newborns) • Human papillomavirus (HPV) (for girls)
12.	Take part in organized cancer screening programmes for: • Bowel cancer (men and women) • Breast cancer (women) • Cervical cancer (women)

Neoplasms will continue to be a major source of human disease and death. Considerable efforts are made in the public and private domains to develop

effective therapeutic approaches. Even if major discoveries in the clinical management of cancer patients will be accomplished in the near future, the changes will mainly affect the affluent part of the world population. Prevention of the known causes of cancer remains the most promising approach to reducing the consequences of cancer, in particular in countries with limited resources. Control of tobacco smoking and of smokeless tobacco products, moderation in alcohol consumption, processed and red meat intake, increased ingestion of vegetable and fruits, reduced overweight and obesity, increased physical activity, avoidance of exposure to solar radiation, control of known occupational carcinogens, and vaccination, eradication, and treatment against known carcinogenic infectious agents are the main approaches.

8.3

Chronic obstructive pulmonary disease and asthma

Craig M. Riley, Jessica Bon, and Alison Morris

Introduction

The most common non-malignant respiratory conditions characterized by airway dysfunction are referred to collectively as obstructive airway diseases and include chronic obstructive pulmonary disease (COPD) and asthma. Both conditions are highly prevalent and have increased dramatically worldwide in the past few decades. COPD is now the fourth leading cause of death worldwide (WHO 2007), and both COPD and asthma have a profound impact on quality of life for patients and their families. In this chapter, we review definitions, epidemiology, and risk factors for COPD and asthma.

Definitions

COPD

Traditionally, COPD has been defined as irreversible airflow obstruction due to chronic bronchitis and emphysema that progresses over time (Petty 2006). The Ciba Guest Symposium (Ciba Foundation Guest Symposium 1959) and the American Thoracic Society symposium (Committee on Diagnostic Standards for Nontuberculous Respiratory Diseases 1962) proposed the first formal definitions of chronic bronchitis and emphysema respectively. Current definitions are still largely based on these initial definitions; that is, chronic bronchitis is defined clinically as the presence of chronic productive cough for at least 3 consecutive months in 2 consecutive years, and emphysema is a pathological diagnosis of an increase in the size of the distal airspaces and destruction of their walls without obvious fibrosis (American Thoracic Society Committee on Diagnostic Standards 1962). The most

recent definitions of COPD as reported in the American Thoracic Society (ATS), European Respiratory Society (ERS), and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines (Agusti et al. 2017) emphasize the inflammatory response to noxious particles and gases as the predominant pathological feature of the disease and have parted from the definition of COPD as being a syndrome of chronic bronchitis and emphysema. The widely accepted GOLD definition (Agusti et al. 2017) states that COPD is:

> a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases. (Agusti et al. 2017)

Although no longer specifically included in the definition, chronic bronchitis and emphysema remain important causes of the chronic airflow limitation characteristic of COPD. The three main components (inflammation, airflow limitation that is not fully reversible, and a gradual loss of lung function over time) represent the major pathophysiological events leading to the symptoms typically expressed by those with COPD: chronic and progressive cough, sputum production, and dyspnoea.

Clinical assessment of COPD

Spirometry is an essential tool in the clinical diagnosis of COPD. COPD is still traditionally diagnosed based on the post-bronchodilator ratio of the forced expiratory volume in 1 second (FEV1, the volume of air exhaled in the first second of expiration) to the forced vital capacity (FVC, the maximum volume of air that can be forcibly expired). A cut-point of 70% continues to be widely used (Agusti et al. 2017), but increasing attention has been paid to utilizing the lower limit of normal as a cut-off for the FEV_1/FVC ratio to define obstruction (Vaz Fragoso et al. 2016). Use of this cut-off has the potential advantage of limiting underdiagnosis in younger adults and overdiagnosis in the elderly, but to date, a clear clinical advantage to utilizing the lower limit of normal over a fixed cut-off has not been demonstrated (Calverley et al. 2018). Bronchodilator treatment prior to spirometry is important as it establishes whether obstruction is irreversible and thus helps to distinguish COPD from asthma. In COPD with mild or moderate obstruction, the FVC is generally unaffected, or only marginally

affected; however, FEV_1 is reduced. In severe obstruction, air-trapping may lead to a reduction in FVC as well as FEV_1, which can be differentiated from restriction by analysis of flow volume loops or lung volume measurements by nitrogen washout or plethysmography. Patients with COPD also frequently have a low diffusing capacity for carbon monoxide (DLco) because of the destruction of lung tissue resulting in decreased gas transfer.

The degree of severity of obstruction in those with FEV_1/FVC less than 70% is usually based on the patient's FEV_1. The 2018 GOLD criteria classify obstruction severity in COPD into four stages (Agusti et al. 2017) (Box 8.3.1). While the degree of obstruction is useful for monitoring the progression of disease and correlates strongly with mortality (Mannino et al. 2003), FEV_1 is less predictive of other patient-centred outcomes including symptom burden and acute exacerbations (Han et al. 2013). As these patient-centred outcomes are the major targets of common treatment modalities, recent GOLD guideline updates have developed risk-stratification tools and treatment algorithms that incorporate symptom scores and exacerbation risk independently of spirometry discussed next (Agusti et al. 2017).

Box 8.3.1 GOLD criteria of COPD severity

- Stage I, mild: $FEV_1 \geq 80\%$ predicted.
- Stage II, moderate: $50\% \leq FEV_1 \geq 80\%$ predicted.
- Stage III, severe: $30\% \leq FEV_1 \geq 50\%$ predicted.
- Stage IV, very severe: $FEV_1 < 30\%$ predicted.

Global Initiative for Chronic Obstructive Lung Disease (GOLD). Global Strategy for the Diagnosis, Management and Prevention of Chronic Obstructive Pulmonary Disease: 2018 Report.

Epidemiologic assessment of COPD

The methodology used to assess COPD prevalence in epidemiologic cohorts and population-based studies often leads to underestimation of the true prevalence. In population-based surveys, COPD is often defined on the basis of: (1) self-report of a doctor diagnosis of COPD, bronchitis, or emphysema; (2) self-report of respiratory symptoms; and (3) spirometry with or without

prior bronchodilator treatment. Self-report of a clinical diagnosis significantly underestimate the true disease prevalence (Halbert et al. 2006). More accurate approaches incorporate both spirometry, exposure history, and respiratory symptom assessment (Buist et al. 2007).

The variable use of bronchodilators significantly complicates large population-based spirometry surveys, and many studies unfortunately do not collect post-bronchodilator measurements. Failing to check for reversibility of airflow obstruction (using pre- and post-bronchodilator spirometry) may result in an overestimation of the prevalence of COPD. In population studies comparing pre- and post-bronchodilator spirometry to examine COPD prevalence, using post-bronchodilator values lowered the estimated rate of airflow obstruction by 30–50% (Tilert et al. 2013). Therefore, the use of post-bronchodilator spirometry to determine the diagnosis of COPD in population-based studies is strongly recommended.

Asthma

The word ‘asthma’ comes from a Greek word meaning ‘panting’ (Keeney 1964), but reference to asthma-like symptoms can also be found in ancient Egyptian, Hebrew, and Indian medical writings (Ellul-Micallef 1976). There were clear observations of patients experiencing attacks of asthma in the second century, and evidence of disordered lung anatomy as far back as the seventeenth century (Willis 1678). The definition of asthma initially proposed at the Ciba Foundation conference in 1959 (Ciba Foundation Guest Symposium 1959) and endorsed by the ATS in 1962 (American Thoracic Society Committee on Diagnostic Standards 1962) is that ‘asthma is a disease characterized by wide variation over short periods of time in resistance to flow in the airways of the lung’. Although these features receive lesser prominence in some current definitions given the now-recognized importance of airways inflammation, they are still integral to the current Global Initiative for Asthma (GINA) description of asthma as:

> a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness and cough that vary over time and in intensity, together with variable expiratory airflow limitation. (GINA 2018)

This definition of asthma encompasses both the pathophysiological mechanisms (in chronic airway inflammation and variable airflow

obstruction due to bronchial hyperreactivity) and their downstream effects on patients by which providers clinically identify and diagnose this disease.

Clinical assessment of asthma

There is no single test or pathognomonic feature that defines the presence or absence of asthma. Furthermore, the variability of the condition means that evidence of it may not be present at the initial assessment. Thus, a diagnosis of asthma is made on the basis of the clinical history in combination with physical examination and respiratory function tests over a period of time. As a result, asthma is subject simultaneously both to significant under- and overdiagnosis. Studies have shown both a significantly lower prevalence of physician-diagnosed asthma in the community as compared to the prevalence of asthma-like symptoms, suggesting that 20–70% of asthmatics are undiagnosed (Aaron et al. 2018). Furthermore, there are several disorders that have signs and symptoms (such as wheeze) that can be confused with or mimic aspects of asthma and lead to overdiagnosis in approximately 1/3 of cases (Aaron et al. 2017); common conditions mistaken for asthma include gastroesophageal reflux disease, chronic bronchitis, lower respiratory tract infections, bronchiectasis, vocal cord dysfunction, obesity, and COPD.

There are a number of tests that facilitate the diagnosis and monitoring of asthma. Measurements of lung function are the most frequently used and provide important information on airflow variability, reversibility, and severity. Airflow limitation is generally measured using spirometry or a peak expiratory flow (PEF) meter. PEF meters are inexpensive and easy to use, but they are less precise than spirometry and may underestimate the degree of airflow limitation. Therefore, spirometry is preferred for diagnosis when available. Because of the importance of bronchial hyperreactivity and bronchodilator reversibility, guidelines emphasize the importance of conducting spirometry or PEF measurements both before and after bronchodilator treatment when assessing lung function in asthma (GINA 2018). Pre- and post-bronchodilator testing is important since it establishes if obstruction is irreversible and allows distinction from COPD. Reversibility of FEV_1 of $\geq$ 12% and $\geq$ 200 mL from the pre-bronchodilator value is generally accepted as a valid indication of asthma (GINA 2018). However, due to the highly variable nature of the condition, repeated lung function tests are required, as some patients may not display reversibility when their

asthma is well-controlled, and reversibility may be present in non-asthmatics.

In individuals with asthma symptoms and normal lung function, bronchial hyperresponsiveness (BHR) testing may be used as a diagnostic aid. BHR constitutes airway narrowing to non-specific stimuli, such as exercise, cold air, and chemical irritants. Although BHR is related to asthma, it may occur independently of asthma, and vice versa, which makes BHR testing insufficient to diagnose asthma in isolation.

An increasing number of tests are available to measure non-invasive markers of airway inflammation, including sputum induction tests, exhaled nitric oxide, and measurements of inflammatory markers in exhaled breath condensate. While these tests may be useful in establishing asthma phenotypes and identifying patients who are more likely to respond to optimal treatment, they have as yet to be convincingly demonstrated to aid in asthma diagnosis (Colak et al. 2018).

There have been several approaches used to categorize asthma (Wenzel 2012). Until recently, asthma has most commonly been clinically classified on the basis of severity using GINA criteria (GINA 2006), which subdivided asthma into four categories (intermittent, mild persistent, moderate persistent, and severe persistent). More recent guidelines (GINA 2018) have suggested that clinical categorization should be based on the current level of asthma control (controlled, partly controlled, and uncontrolled), which may more adequately address the individual clinical needs of the patient. Other categorizations of asthma exist based on type of inflammation seen such as atopic, eosinophilic, or TH-2 high (Tran et al. 2016). Although these asthma endotypes may overlap, they may represent different mechanistic pathways and respond differently to treatment.

Defining asthma in epidemiological surveys

Defining and diagnosing asthma in population-based epidemiological surveys poses even greater difficulties than defining asthma in individuals. As a result, asthma prevalence surveys usually focus on self- or parental-reported ‘asthma symptoms’ rather than diagnosed asthma. This approach allows a large number of participants to be rapidly surveyed without great cost. Of the symptoms clinically associated with asthma, epidemiological studies have shown that wheezing is the most important symptom for the

identification of asthma, and thus questionnaires used to assess asthma prevalence are often based on wheezing. An alternative approach to symptom questionnaires has been to use more ‘objective’ measures such as BHR testing, either alone or in combination with questionnaires. BHR may not be more reliable than questionnaire alone, in part due to the variability of BHR at the time of assessment.

Overlap syndrome

Although reversibility of airway obstruction (or the lack thereof) is the primary clinical characteristic used to define either asthma or COPD, it is increasingly recognized that patients may have features of both diseases (Woodruff et al. 2017). It is often difficult to clearly distinguish and diagnose the two conditions, particularly in older patients. These observations have led to the description of asthma-COPD overlap (ACO), in which obstructive respiratory disease shows features of both asthma and COPD (Woodruff et al. 2017). The epidemiology of ACO is not well-understood, and attempts to characterize its prevalence and associations have been limited by different definitions across various studies. Approximately 17% of patients diagnosed with either asthma or COPD would meet criteria for ACO, and these patients are at higher risk for exacerbation, hospitalization, and disability compared to either population alone (Vaz Fragoso et al. 2017; Woodruff et al. 2017). Further work needs to be done to clearly define this syndrome to better identify long-term outcomes and efficacious treatment strategies as ACO patients have generally been excluded from treatment trials of asthma and COPD.

Epidemiology, risk factors, and prevention of COPD

Epidemiology of COPD

COPD is a major global cause of mortality and morbidity, with exacerbations leading to frequent hospitalization. Despite the large personal, societal, and economic burden, it has been difficult to accurately estimate the true prevalence and it is often underdiagnosed. According to the World Health Organization, the global burden of COPD is estimated at 210 million

people with 65 million suffering from moderate to severe disease (WHO 2007). It is also a major cause of healthcare costs and lost productivity.

European epidemiological studies of COPD show prevalence estimates for COPD of 2 to greater than 10% (WHO 2007) (Fig. 8.3.1). These differences in prevalence estimates are presumed to be attributable to differences in risk exposures or population characteristics, but methods and definitions used to measure COPD may also play a role. Definitions of COPD used in these studies vary from a doctor's diagnosis of COPD, to more rigid definitions based on pathology and/or pulmonary lung function testing.

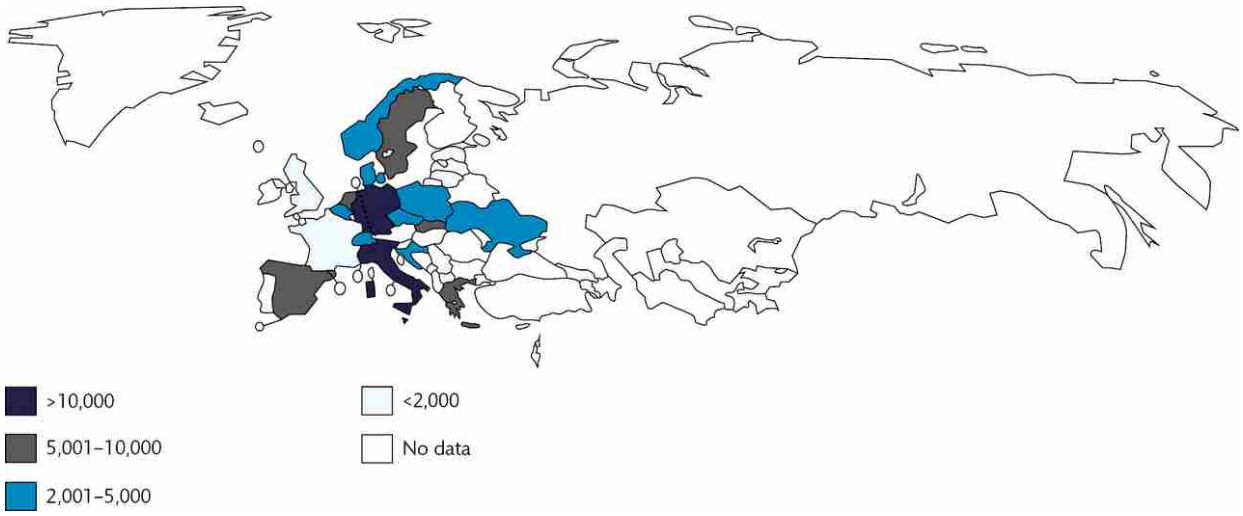

Fig. 8.3.1 Prevalence rate (1/100,000) of COPD in Europe.

http://apps.who.int/iris/bitstream/handle/10665/43776/9789241563468_eng.pdf

Halbert and co-workers (Halbert et al. 2003) assessed the reasons for conflicting prevalence estimates in the literature. They selected studies that had estimated population-based COPD prevalences and clearly described methods used to obtain these estimates. In total, 32 studies, representing 17 countries and eight WHO regions, presenting prevalence data for COPD were identified and reviewed. Prevalence estimates were based on spirometry (11 studies), respiratory symptoms (14 studies), patient-reported disease (10 studies), or expert opinion. The reported prevalence of COPD ranged from 0.23 to 18.3%, with the lowest prevalences (0.2 to 2.5%) being those based on expert opinion. Sixteen studies had measured rates that could

confidently be extrapolated to an entire region or country. All 16 studies were conducted in Europe or North America, and in most, the prevalence was between 4% and 10%. However, in some studies, COPD prevalence may be higher. For example, preliminary data from 13,301 participants in the LifeLines cohort study performed in the Netherlands showed that 1920 out of 13,301 subjects had GOLD stage I or higher (14%) (i.e. 1,402 had GOLD stage I, 494 GOLD stage II, and 24 GOLD stage III/IV). In a later study, Halbert et al. (Halbert et al. 2006) identified 101 COPD prevalence estimates from 28 countries during the 1990–2004 time period. The pooled prevalence of COPD was 7.6%; the prevalence of chronic bronchitis alone was 6.4%, and the prevalence of emphysema alone was 1.8%. The pooled prevalence of COPD based on spirometry was 8.9%.

Although the most accurate prevalence data are from high-income countries (HCs), the WHO estimated that almost 90% of the 3.22 million deaths estimated to be attributable to COPD in 2015 occurred in low- and middle-income countries (LMICs) (WHO 2013). Few epidemiologic studies have provided truly comparable international prevalence estimates for COPD. The establishment of the Burden of Obstructive Lung Disease (BOLD) Initiative to assess the global burden of COPD allows more valid comparisons of the prevalence of COPD over time and across ethnopolitical regions (Buist et al. 2007). This study included 9,425 participants from 12 centres in 12 countries including China, Turkey, Austria, South Africa, Iceland, Germany, Poland, Norway, Canada, the United States, Philippines, and Australia. The study showed considerable variation in COPD prevalences, with GOLD stage II or higher COPD in women ranging from 5.1% in Guangzhou, China, to 16.7% in Cape Town, South Africa. In men, it ranged from 8.5% in Reykjavik, Iceland to 22.2% in Cape Town, South Africa. Using a similar study design, the Latin American Project for the Investigation of Obstructive Lung Diseases (PLATINO) studied the prevalence of COPD in 5,315 study participants in five Latin American centres (Mexico, Venezuela, Brazil, Chile, and Uruguay) (Menezes et al. 2005). Crude prevalence rates of COPD ranged from 7.8% in Mexico City, Mexico, to 19.7% in Montevideo, Uruguay. Age and smoking did not fully explain the international variation in disease prevalence, suggesting a role for additional risk factors.

Future prevalence and burden of COPD

Assessing the future prevalence and burden of COPD requires the consideration of changing population distributions and smoking habits. A recent study (Burgel et al. 2018*)* modelled COPD prevalence by 2025 based on data from France and predicted a fourfold increase in prevalence of more severe COPD with disproportionate increases in women and individuals over the age of 75. Globally, COPD is projected to be the third-leading cause of death in both men and women with an estimated 4.57 million deaths annually, a 42% increase (WHO 2007). While this increase is driven primarily by LMICs where the mortality share of COPD is expected to increase primarily due to increases in smoking, the population mortality rate of COPD is projected to increase in every economic group studied (WHO 2013). Mortality rates are at risk to substantially increase with economic progress and the adoption of Western practices, particularly in Asia, Africa, and the Middle East (Bilano et al. 2015). In addition to mortality, COPD morbidity is on the rise. COPD is projected to be the seventh cause of morbidity worldwide by 2030 (WHO 2007*)*. Analysis from the Global Burden of Diseases, Injuries and Risk Factors 2015 study suggests that sub-Saharan Africa and South and Southeast Asia suffer from the highest disability-adjusted life year burdens of COPD (GBD 2015 Chronic Respiratory Disease Collaborators 2017).

What is most striking about the epidemiology of COPD has been the change in prevalence in women (Aryal et al. 2013). Due to increased smoking rates in women and women taking up smoking at younger ages in recent decades, women now are about equal to men in COPD prevalence with similar mortality (WHO 2007). This trend is expected to be continue in LMICs in response to both increases in smoking, continued biomass exposure, and increasing air pollution. Nonetheless, women with COPD remain less likely to be diagnosed and treated (Miravitlles et al. 2005).

Risk factors for COPD

Cigarette smoking

COPD usually occurs with exposure to an inhalational irritant. In developed countries, this exposure is predominantly cigarette smoke. Cigarette smoke contains thousands of toxic chemicals including nicotine, acetone, and tar. Smoke inhalation stimulates an inflammatory reaction with recruitment of inflammatory cells to the lung that results in loss of lung parenchyma and

airway obstruction. Smoking also leads to impaired mucociliary clearance, increased oxidative stress, and protease/antiprotease imbalance. Second-hand smoke (SHS) exposure increases risk of COPD and negatively impacts lung function by similar mechanisms.

There is a well-established association between current and cumulative smoking and COPD, and adult smokers experience a faster FEV_1 decline than non-smokers. This excess decline in lung function may return to normal levels of ageing-related decline after smoking cessation, emphasizing the importance of early tobacco cessation interventions. Few data are available on the incidence of COPD according to detailed smoking habits. Analysis of the Copenhagen City Heart Study confirmed a higher incidence of COPD in smokers than non-smokers, with 27% of participants who continued to smoke over a 25-year period developing COPD as defined by GOLD stage II–IV COPD, compared with 5.7% of non-smokers (Lokke et al. 2006). The longitudinal Vlagtwedde/Vlaardingen Cohort Study (with a follow-up of 25 years) also showed that persistent cigarette smokers, recidivist smokers, variable pipe/cigar smokers, and subjects who stopped smoking had an increased risk of developing COPD compared to never smokers. The risks of developing COPD in sustained ex-smokers, starters, brief smokers, and persistent pipe/cigar smokers were not significantly different.

Less is known about the relative risk of non-cigarette smoking habits, including cigars, traditional pipes, water pipes, marijuana, and electronic cigarettes and vaporizers. Observational studies of these modalities will be challenging given the heterogeneity of exposure burden across brands and devices; however, it is likely that relative risk is significant given similar immune and inflammatory effects to cigarette smoking. At this time, evidence about safety and risk is insufficient to recommend alternate inhaled substances as a means of tobacco cessation.

Indoor biomass exposures

Although cigarette smoking is the most common inhalational exposure related to COPD, biomass exposure from fuels burned for heating and cooking (WHO 2007) can lead to COPD as well. Such indoor air exposures are important risk factors in low-income countries where biomass fuels (wood and crop residues) and coal fuels are often used for heating and cooking without appropriate ventilation. WHO estimates that approximately 3 billion people, predominantly in LMICs, cook with solid fuels and

kerosene resulting in household air pollution and increased COPD risk (WHO 2007). It is estimated that this exposure results in 25% of premature deaths from COPD in LMICs (WHO 2007). Recently, it has been recognized that poor inner-city and rural areas of wealthier countries have similarly high rates of indoor biomass exposure (Levy et al. 2018). While COPD is also thought to be related to outdoor pollution levels, current evidence is not conclusive regarding the magnitude of this risk (Schikowski et al. 2014).

Occupational exposures

Occupational exposure to dusts, gases, and fumes are also associated with the rate of decline in FEV_1 and the development of COPD. Some examples of occupational risk factors for COPD are coal dust, silica dust, oil mists, welding fumes, and organic dusts including cotton, grain, and wood. It is estimated that 15 to more than 20% of COPD is caused by occupational factors (Lytras et al. 2018). For example, the Third National Health and Nutrition Examination Survey in the United States found that approximately 20% of COPD cases in the United States were attributable to work-related exposures (Hnizdo et al. 2002). The proportion was even higher (approximately 30%) in never smokers. Individuals who have occupational exposures and also smoke have an even greater COPD risk.

HIV

Pulmonary disease has been a cause of significant morbidity and mortality in HIV-infected individuals since the beginning of the AIDS epidemic. COPD and emphysema were reported to be more common in HIV-infected individuals prior to the advent of effective antiretroviral therapy (ART)(Diaz et al. 2000) and prevalence of lung function imparirment has not decreased significantly in recent years. Population studies in the Veterans Administration found that a diagnosis of COPD was more common in HIV-infected individuals than in similar HIV-uninfected individuals in the current era (Crothers et al. 2011), and studies of pulmonary function have demonstrated that HIV is an independent risk factor for impairment of diffusing capacity for carbon monoxide, a lung function abnormality that reflects emphysema/COPD as well as pulmonary vascular disease (Crothers 2013; Fitzpatrick et al. 2013). In addition, over half of outpatient HIV-

infected cohorts report respiratory symptoms (Gingo et al. 2014). Although COPD occurs in HIV-infected individuals who have never smoked, it is still most common in smokers, making smoking cessation critical in this population.

Genetic risk factors

The contribution of genetics to COPD is exemplified by the heritable disorder alpha-1 antitrypsin deficiency (AATD). Individuals with AATD have a mutation in the SERPINA1 gene that results in abnormal structure of or decreases in endogenous levels of alpha-1 antitrypsin, a critical antiprotease whose absence can lead to breakdown of lung tissue and COPD in early life (Piitulainen and Eriksson 1999). The interplay between inhalational exposure and genetics is well-illustrated by the observation not all patients with AATD will develop COPD, and those who smoke experience lung function decline 2–4 times faster than never smokers with AATD (Piitulainen and Eriksson 1999). Similarly, not all individuals with a heavy cigarette smoking burden develop COPD.

Other than the single gene AATD, genetic factors in COPD are likely multifactorial and have been difficult to study. Since COPD is predominantly expressed in later years, the parents of individuals with COPD have often already died, and the children of individuals with COPD are likely to be too young to have significant fixed airway obstruction. Initial genetic studies on COPD included small numbers of subjects and applied different definitions of disease, hampering a valid comparison between studies and increasing the likelihood of spurious results. Many positive results from genetic studies of COPD have therefore not been replicated. Furthermore, lack of replication might also be due to the apparent difficulties of extrapolating results from one population to another, such as Asians and Caucasians.

Most studies on genetics of COPD have focused on genes that are involved in the processing of various tobacco smoke products, oxidative stress, or in the protease/antiprotease balance. In particular, variations in the genes encoding enzymes that detoxify cigarette smoke products (and are thus protective against oxidative stress) may explain why only a proportion of smokers develop COPD. Candidate genes identified in this way include *EPHX1*, *ADAM33*, *MMP1*, *GSTP1*, *GSTT1*, *GSTM1*, *HMOX1*, and *SERPINA1* (Postma et al. 2011).

Genome-wide association (GWA) studies are applied to identify genetic loci that are associated with disease using markers throughout the genome, rather than selected on the basis of their assumed biological function. The first COPD GWA study identified variants in the nicotinic acetylcholine receptor (nAChR) subunit genes, *CHRNA3/5* (Pillai et al. 2009) which were confirmed in later studies (Kim and Lee 2015). SNPs in this nicotinic cluster have previously been related to smoking habits and addiction, raising the question of whether these genes are directly involved in lung function loss leading to COPD *per se*, or act indirectly through effects on nicotine addiction. Other GWA studies have identified *IREB2*, which regulates cellular iron that is associated with pulmonary artery enlargement in COPD, *AGER*, the soluble protein product of which (sRAGE) is a potential biomarker for emphysema presence and progression, and hedgehog interacting protein (*HHIP*) which plays a role in lung development and injury response (Kim and Lee 2015). A recent whole genome sequencing study of patients with severe COPD confirmed findings of variants of HHIP and CHRNA3 genes as influential (Prokopenko et al. 2018). GWA studies have also been complemented and validated by quantitative trait loci (QTL) analyses, which allow incorporation of gene expression, methylation, and many other data types (Morrow et al. 2018). To date, discovery of these genetic variations has not led to novel therapies.

COPD prevention

The mainstay of COPD prevention is reducing exposure to cigarette smoke and to indoor air pollutants. Barriers to prevention efforts include the underdiagnosis of COPD, lack of public awareness of the disease, and inadequate policies for preventing exposures. In LMICs, respiratory disease prevention efforts may be more focused on communicable pulmonary diseases such as tuberculosis and pneumonia. The Centers for Disease Control identified four main goals for COPD prevention (CDC 2011) (Box 8.3.2). The WHO recommends five policies for decreasing tobacco use that would be expected to impact COPD incidence (Box 8.3.2).

Box 8.3.2 Centers for Disease Control goals for COPD prevention

- Surveillance and evaluation: Improving public health data
- Public health research and prevention strategies: Improving understanding of COPD
- Programmes and policies: Improving collaboration among stakeholders
- Communication: Improving awareness of COPD

World Health Organization policies for controlling tobacco use

- Promotion of smoke-free environments
- Support for tobacco cessation programmes
- Health warnings on cigarettes
- Bans on tobacco advertisers
- Higher taxes on tobacco products

From Centers for Disease Control and Prevention. Public Health Strategic Framework for COPD Prevention. Atlanta, GA: Centers for Disease Control and Prevention; 2011. Available at www.cdc.gov/copd; World Health Organization. World Health Statistics 2008.

Public health efforts aimed at reducing smoking rates and encouraging smoking cessation are of great importance. Improved ventilation measures to reduce indoor pollutants in houses decrease both the prevalence and morbidity of COPD (Zhou et al. 2014). For example, a systematic review and meta-analysis of improved biomass cookstoves found decreased COPD and respiratory symptoms in women (Thakur et al. 2018). The greatest benefits in COPD prevention may be in targeting those patients at risk for impaired lung development or rapid lung function decline in the setting of harmful exposures—assuming that they can be identified *a priori*, which remains the topic of ongoing research efforts.

Epidemiology, risk factors, and prevention of asthma

Epidemiology of asthma

Like COPD, asthma is prevalent worldwide with an estimated 300 million people affected (WHO 2007). Its prevalence varies by country (Fig. 8.3.2), and it is increasing worldwide, with exact rates depending on environmental exposures, lifestyle factors, and urbanization (WHO 2007). Given the strong relationship of asthma with allergy, its increasing prevalence mirrors that of allergy. Despite availability of multiple therapeutic agents for asthma, mortality is about 250,000 deaths worldwide each year (WHO 2007). Asthma is also highly morbid, leading to both missed workdays and missed school given its frequency in children. Both morbidity and mortality from

asthma can be linked to lack of access to medical care and adequate therapies.

Two multidecade survey studies, the European Community Respiratory Health Survey (ECRHS) and the International Study of Asthma and Allergies in Childhood (ISAAC), started in the early 1990s and provided insight into changing asthma prevalence trends. Both studies showed striking international differences in asthma symptom prevalence with a particularly high prevalence of reported asthma symptoms in English-speaking countries including the British Isles, New Zealand, Australia, the United States, and Canada (Asher et al. 1995; Burney et al. 1996; Asher et al. 1998; Beasley et al. 1998). Among the non-English-speaking European countries, both studies showed high asthma prevalence in Western Europe, with lower prevalences in Eastern and Southern Europe. These studies also provided insights into

asthma in Africa and Asia. These areas generally showed relatively low asthma prevalence (Fig. 8.3.2). In particular, prevalence was low in developing countries such as China and Indonesia whereas more affluent Asian countries such as Singapore and Japan showed relatively high asthma prevalence rates. The ISAAC survey also showed that centres in Latin America had particularly high symptom prevalence. Interestingly, Latin America showed higher prevalences than Spain itself, in contrast to the general tendency for more affluent countries to have higher prevalence rates.

Future prevalence and burden of asthma

Global asthma trends have exhibited either slight increases or plateaus in prevalence. While many theories have been proposed for divergent studies, there is no clear explanation. Countries with similar socioeconomic and genetic compositions have experienced divergent prevalence rate progression (de Korte-de Boer et al. 2015; Backman et al. 2017). The asthma prevalence in many affluent countries has peaked or even begun to decline, whereas asthma symptom prevalence continues to rise in less affluent countries. Changes in prevalence of asthma may result from changes in methods of diagnosis, but changes in environmental risk factors may also play a role.

Risk factors for asthma

Atopy

Atopy, or the presence of IgE antibodies to specific allergens, is strongly associated with asthma within populations. About half of asthma cases are linked to atopy (Arbes et al. 2007), although there is a lower population attributable risk (~20%) in less affluent populations and risk is variable (Weinmayr et al. 2007). IgE levels in serum are associated with a diagnosis of asthma and with presence of airway hyperresponsiveness. Although atopy is a risk factor for asthma, it represents a biological response to various exposures (e.g. allergen exposure) which may be modified by susceptibility factors (genetic and/or environmental).

Allergen exposure

In sensitized asthmatics, allergen exposure can trigger asthma attacks and prolonged exposure can lead to the prolongation and exacerbation of symptoms; however, a causative role of allergen exposure in development of asthma is less clear. The key study linking allergen exposure in infancy to the subsequent development of asthma is that of Sporik et al. (1990) who followed 67 children with a family history of atopy. Subsequent longitudinal birth cohort studies found little or no association between early dust mite allergen exposure and asthma later in childhood (Tepas et al. 2006). A recent systematic review reported that visible mould or mould odour was associated with respiratory symptoms, wheezing, and development of asthma in children (Caillaud et al. 2018).

Gender and ethnicity

There are a variety of demographic factors that are associated with asthma including age, gender, and ethnicity. Asthma incidence and prevalence are consistently lower in females than in males before age 12 years, whereas during adolescence and adulthood there is evidence of higher incidence and prevalence in females (Kimbell-Dunn et al. 1999). The reasons for this disparity are unclear, but could be related to later age of asthma onset in childhood and adolescence in females and differences between boys and girls in exposures, airway size, atopy, and frequency and severity of lower respiratory tract illnesses. These differences could also be due to hormonal influences. Hormones likely play a role as demonstrated by premenstrual asthma which manifests as worsening of asthma symptoms around the time of menstruation and the observation that pregnancy can often increase or decrease asthma control. Ethnicity also appears to influence asthma risk. For example, Puerto Ricans in the US have a high rate of asthma while Mexicans in the US have very low rates, a finding that has been termed the ‘Hispanic paradox’ (Rosser et al. 2014).

Socioeconomic status

The impact of socioeconomic status on asthma is conflicting. Studies in the 1960s and 1970s suggested that asthma is more common in children in the higher socioeconomic status (SES); however, severe asthma appears to be more common in children in lower income groups (Stewart et al. 2001) and in some disadvantaged ethnic groups (Rosser et al. 2014). These findings

could represent either a greater prevalence of asthma in disadvantaged groups, or increased severity due to environmental factors (e.g. SHS, nutrition, occupational exposures) or inadequate disease management and poor access to healthcare.

Obesity

Studies have shown an association between body weight and asthma in both adults and children with prospective studies suggesting that obesity precedes asthma (Ronmark et al. 2005; Noal et al. 2011). However, findings supporting this association have not been entirely consistent (Noal et al. 2011). The evidence linking obesity and atopy is also conflicting with some studies suggesting that obesity is associated with asthma independent of atopy (Visness et al. 2010; Holguin et al. 2013) and with the identification of asthma clusters containing predominantly obese, non-atopic patients (Moore et al. 2010).

Diet

Diet throughout the lifespan may impact asthma risk and severity. Many studies including several infant cohort studies have investigated the effects of breastfeeding on allergies and asthma with some studies showing protective effects, some showing no effect, and others suggesting that breastfeeding is a risk factor (Friedman and Zeiger 2005; Kramer et al. 2007; Matheson et al. 2007). Other nutritional factors may also play a role in the aetiology of asthma. In particular, it has been speculated that the increase in asthma prevalence may be due to a change in dietary patterns in the past few decades, that is, as cultures have become more ‘Westernized’ they have shifted from growing and consuming locally grown foods to consuming more processed foods and less fresh produce. This hypothesis is supported by results from the ISAAC Phase II and other studies (Chatzi and Kogevinas 2009; Nagel et al. 2010) that found that fruit, vegetable, and fish consumption was associated with a lower prevalence of current wheeze and asthma. Development of some atopic disorders has been associated with exposures to n-6 versus n-3 fatty acids, but this finding was not consistent for all atopy/allergies (Almqvist et al. 2007; Notenboom et al. 2011). Maternal folate supplementation during pregnancy has also been suggested as a risk factor for asthma in childhood.

Vitamin D

There has been conflict in studies suggesting an association between vitamin D deficiency and asthma risk. Several studies based on dietary questionnaire findings have associated higher levels of maternal vitamin D with lower rates of asthma in children (Muehleisen and Gallo 2013) and low serum vitamin D levels in asthmatic children and adults with asthma severity and poor asthma control (Korn et al. 2013). A meta-analysis of double-blind, randomized, controlled trials of vitamin D found that vitamin D resulted in decreased rate of asthma exacerbations that required corticosteroid treatment (Joliffe et al. 2017*)*, but not all trials examining vitamin D supplementation have not been successful in decreasing asthma rates or improving outcomes.

Outdoor air pollution

The role of outdoor air pollutants (particulate matter (PM), ozone, nitrogen dioxide (NO_2), and sulphur dioxide) in asthma has been extensively studied (Guarnieri and Balmes 2014). An association between measures of distance to major roads or traffic density and asthma symptoms has been demonstrated in a number of European countries (WHO 2005). Also, a large number of studies have reported associations between direct measurements of air pollution levels and exacerbation of pre-existing asthma, both in children and adults (WHO 2005). Some studies, including a birth cohort study (Brauer et al. 2007), have also suggested that air pollution may cause *new onset* of asthma and allergic disease. In particular, several large prospective studies have suggested a role for ozone (McDonnell et al. 1999; McConnell et al. 2002), although significant associations with some asthma outcomes were also shown for PM2.5, soot, and NO_2 (Brauer et al. 2007).

Indoor air pollution

Little is currently known about the contribution of indoor air pollutants (other than SHS) to the incidence and prevalence of asthma. Nitrogen dioxide from burning fossil fuels has received the most attention while sulphur dioxide from burning sulphur-containing coal or gas, mosquito coil smoke, and formaldehyde from wood preparation have also been considered. Particulates from open or closed wood and coal burning fires have received less attention in HCs (Oluwole et al. 2017), but have been studied in LMICs where very high indoor levels have been encountered. Damp indoor

environments and indoor fungal exposure may also play a role as demonstrated in a large number of studies conducted across many geographical regions (Douwes and Pearce 2003; Karvonen et al. 2018). Further study is needed to determine whether programmes to decrease indoor PM concentrations or humidity levels can prove effective in decreasing asthma prevalence in addition to decreasing respiratory morbidity (Beasley et al. 2015).

Tobacco

Although smoking is a primary risk factor for COPD, it may also influence asthma, both if asthmatic patients smoke or if they are exposed to SHS either before or after birth. The evidence for a role of tobacco smoke in asthma is strongest for increases in severity in children who already have asthma; however, an increasing number of studies also show positive associations between SHS and incidence of asthma (Accordini et al. 2012). Several meta-analyses concluded that household SHS exposure was associated with the incidence of new-onset asthma and incidence of wheezing in younger and older children (Vonk et al. 2003; Burke et al. 2012).

Occupational exposures

Occupational asthma is the most common occupational respiratory disease in HCs. Estimates of the total proportion of adult occupational asthma range from 2 to 15% in the United States, 15% in Japan (Chan-Yeung and Malo 1994), 5% in Spain (Kogevinas et al. 1996), 2–3% in New Zealand (Fishwick et al. 1997), and 2–6% in the United Kingdom (Meredith and Nordman 1996). A study in the United States estimated that new-onset asthma may be caused by occupational exposures in as many as one of six adult patients (Mazurek et al. 2013). More than 250 agents have been identified as causes of occupational asthma. Some of the most common occupational asthmagens include flour/grain dusts, wood dusts, latex allergens, and isocyanates (Schenker et al. 1998).

Infections

The increase in allergy and asthma contrasts strongly with a reduced prevalence of infectious diseases and corresponding decreased exposure to non-infectious micro-organisms. This reduction in exposure to micro-

organisms has been hypothesized as a possible explanation for the allergy and asthma epidemic (Lambrecht and Hammad 2017) and is commonly referred to as the ‘hygiene hypothesis’. The hygiene hypothesis has been prompted by evidence that overcrowding and unhygienic conditions were associated with a lower prevalence of atopy, eczema, hay fever, and asthma. The hygiene hypothesis may not fully explain the current time and geographical trends in asthma prevalence, but the changes associated with Westernization may be contributing to the global increases in asthma susceptibility and prevalence. It remains unclear as to what is the most important factor in protection from allergies and asthma: dose, route (oral–faecal versus airborne), type of infection (viral versus bacterial versus parasitic) or location (upper versus lower airways or digestive tract).

Viruses

Viral infections are common causes of exacerbations of asthma and associated with hospital admissions in both children and adults. In fact, respiratory viral infections are detected in the majority of asthma exacerbations; of these, about 60% are rhinoviruses (Johnston 2007). Viral infections may also be involved in the development of asthma, but the evidence is less clear. Longitudinal studies have shown that both respiratory syncytial virus and rhinovirus infection increases the risk of subsequent recurrent wheezing and asthma in early childhood (Lemanske et al. 2005; Feldman et al. 2015). The mechanisms of viral-induced asthma are poorly understood, but some evidence suggests that neutrophilic inflammation, impaired innate immune responses and T_H17 signalling dysregulation play crucial roles (Johnston 2007; Das et al. 2017).

Bacteria

Exposures to different types of non-pathogenic bacteria may have differential effects on atopy and asthma beginning at birth. Perinatal microbial exposure with vaginal vs. caesarean delivery is associated with decreased likelihood of developing childhood asthma (Kim et al. 2019), but the specific bacteria involved and whether the relationship is causal is not yet known. Additionally, studies in farming and non-farming environments have suggested that diversity of microbial species, rather than exposure to one particular microbial component, may be particularly protective

(Heederik and von Mutius 2012). Consistent with these findings are observations that daycare centres—known to be associated with a lower prevalence of allergies and asthma in attending children—are associated with considerable bacterial diversity (Lee et al. 2007) as have households with daycare attendees, or with cats and dogs (Maier et al. 2010). Live bacterial exposure may not be required as levels of pro-inflammatory microbial agents (such as bacterial endotoxin) have a significant inverse association between indoor endotoxin levels and atopic sensitization, hay fever, and atopic asthma (Stein et al. 2016).

The microbiome

With the advent of next generation sequencing, we are able to identify many more microbes in environments in the human body than previously detected by traditional culture-based methods. The microbiome, i.e. the total microbes and their genetic content in the human body, may impact asthma development and progression (Lynch and Boushey 2016). It is possible that the microbial composition and function of the lung microbiome alter local immune response and contributes to asthma. Enrichment of certain bacteria in the lungs is associated with inflammation, and studies have found differences in lung bacterial communities in individuals with asthma compared to health controls with enrichment of bacteria such as *Prevotella* and *Haemophilus* (Depner et al. 2017; Durack et al. 2017, 2018). The gut microbiome may also impact asthma as the microbial communities in the gut have profound effects on systemic immunity and can lead to tolerance or inflammation. Dysbiosis during infancy and childhood is associated with wheezing, atopy, and development of asthma (Fujimara et al. 2016). While efforts to change the gut microbiome with probiotics have shown some success in eczema and potentially atopy (Wickens et al. 2013; Cabana et al. 2017), similar benefits in asthma have not been demonstrated and no attempts to directly alter the lung microbiome have been performed. Whether therapeutic alterations in the microbiome or direct targeting of regulatory T cell processes may benefit asthma control or prevention requires further study.

Genetic factors

Asthma is multifactorial in origin and influenced by multiple genes and environmental factors. The heritable component of asthma has been variably estimated to be between 35 and 95% (Ober and Yao 2011). It is not inherited in a simple Mendelian fashion, and particular genetic factors may affect one or more aspects of the complex etiological processes potentially involved in asthma including atopic sensitization, BHR, airway inflammation, and innate immunity. Investigating possible genes for these individual etiological factors is also fraught with difficulties, as control of these factors is also multifactorial. Multiple genes may lead to the same phenotype in different individuals or multiple genes contribute to asthma in a single person. Asthma development, exacerbations, and progression may all involve different environmental triggers and genetic factors, further complicating genetic studies.

Despite the considerable heterogeneity observed, a number of genome linkage and GWA studies have identified several chromosomal regions significantly associated with asthma susceptibility. Several genes on the 17q21 locus including the *ORMDL3/GSDMB* genes have been identified in multiple populations as associated with asthma (Moffatt et al. 2007; Moffatt et al. 2010). In many cases, the involvement of the products of these genes in asthma pathophysiology is feasible, as they are associated with a variety of inflammatory or epithelial/cell-contact pathways and include genes for cytokines such as IL-13 and IL-33. As with COPD, the biological plausibility of these associations has also more recently been strengthened with epigenomic QTL studies (Nicodemus-Johnson et al. 2016; Dijk et al. 2018). However, even when incorporating epigenetic factors, these genes make only a small contribution to overall disease risk on an individual basis, and there may be issues due to the use of different asthma classifications in different studies. While recent meta-analyses of GWA studies have leveraged large cohort sizes into discoveries of further novel disease-associated loci (Demenais et al. 2018), some gene variants may only be associated with certain asthma subtypes and will be difficult to identify with present methodology.

Asthma prevention

Risk factors for asthma may be more difficult to modify than those for COPD, and the heterogeneous nature of the disease complicates public health initiatives. As most asthma begins in childhood, the majority of

prevention efforts have been focused on younger children, although asthma can also present in adulthood. Given potential roles for exposures to indoor allergens and chemicals, strategies targeting the home environment may be effective although these programmes have not been proven as primary prevention (Tanno et al. 2017). Secondary prevention efforts are targeted at improving asthma control and include efforts aimed at decreasing environmental triggers and in providing appropriate asthma controller medications. Encouraging parental smoking cessation is clearly important in both primary and secondary prevention as well as in prevention of COPD in the parent. Programmes targeting improvement in training health professionals, establishing treatment guidelines, and improving public awareness may decrease healthcare costs for asthma. Given the links of asthma with the microbiome, use of probiotics may be helpful as a primary or secondary prevention measure, but their efficacy has not been demonstrated in large-scale studies. As with COPD, prevention efforts face different obstacles in LMICs and HCs.

Treatment of COPD and asthma

The initiation and evaluation of treatment for patients with COPD or asthma is complex. Specific recommendations regarding therapy can be found in disease-specific international (GOLD, GINA, etc) and regional guidelines (Agusti et al. 2017, GINA 2018). All patients with chronic respiratory disease benefit from avoidance of inhalational irritants (particularly cigarette smoke), immunization against common respiratory pathogens (i.e. pneumococcus, influenza), and careful evaluation for comorbid conditions. Patients with mild, intermittent symptoms from either asthma or COPD can be managed with short-acting, as-needed bronchodilators that can be taken during or before activities or exposures that provoke respiratory symptoms. Persistent asthma is managed with inhaled corticosteroids as first-line therapy, with long-acting bronchodilators and other medications including low-dose theophylline and leukotriene receptor antagonists often added in stepwise fashion until disease control is achieved. In individuals with poorly controlled asthma despite these therapies, tiotropium, a long-acting muscarinic antagonist, has been shown to modestly improve lung function and to increase the time to severe exacerbation requiring oral steroid use. Anti-immunoglobin E treatment and anti-interleukin 5 treatment can

likewise be considered in individuals with poorly controlled allergic or severe eosinophilic asthma, respectively (GINA 2018). In contrast, daily COPD pharmacotherapy starts with long-acting bronchodilators; inhaled corticosteroids are typically added for recurrent exacerbations. ACO treatment, due to increased disease severity and combined features of persistent airflow obstruction and airway inflammation (Vaz Fragoso et al. 2017), usually includes both long-acting bronchodilators and inhaled steroids. Patients with functional status limitations can benefit significantly from specialized pulmonary rehabilitation programmes, though the benefits are better established in COPD (Mendes et al. 2010; McCarthy et al. 2015) than asthma.

Conclusions

What do these epidemiological findings tell us about the future of asthma and COPD? The prevalence of COPD is still increasing, and future projections indicate that the global burden of COPD will increase even further. Cigarette smoking remains the greatest cause of COPD, and increasing use in the developing world will ensure that tobacco remains one of the most significant threats to global public health throughout the twenty-first century. Other major causes of COPD including occupational and indoor exposures, particularly among the poor in all countries, remain underappreciated and inadequately addressed. The downstream impact of evolving social trends like electronic cigarettes remains unclear, but demands further study. Different genetic susceptibility to lung function decline from inhalational exposures leads differential likelihood of developing COPD. International differences in COPD prevalence are likely to persist, and research into these disparities may help in targeting smoking cessation and other public health measures towards the highest-risk subgroups.

Global asthma rates continue to increase with wide variation between countries and regions, and the main drivers of asthma development remain incompletely understood. Current public health efforts are thus limited to improving asthma control rather than targeted towards disease prevention. Shifting global patterns in exposure, diet, and occupation are all likely involved in altering the interplay between immunity and environment—through the “hygiene hypothesis” or otherwise—and further study is

required to parse these complex interactions to understand how public health interventions can more effectively decrease the global burden of asthma.

Obesity

Anna Peeters and Tim Lobstein

Introduction to obesity

Globally, the numbers of adults experiencing obesity has increased over sixfold since 1975, from some 100 million to around 670 million in 2016 (Anonymous 2017). In the same period the numbers of children and adolescents living with obesity have risen more than tenfold (from 11m to 125m). While viewed as a condition affecting developed economies, over 15%, some 105m of adults with obesity, live in China and India. Over 20% of children with obesity live in China alone.

Many middle-income countries are now experiencing a nutritional "double burden" of obesity and undernourishment (stunting, underweight, and/or micronutrient deficiencies) simultaneously. These trends are of major concern for population health and healthcare costs and capacity around the world, with obesity increasing the risk of a range of chronic diseases, disability, and early death. There is increasing international agreement on the need to take action to improve population diets and body weight, and a number of countries are now implementing obesity prevention policies such as warnings on food labelling and taxes on sugary drinks. However, further action at global political as well as local community levels are needed to avoid the projected future burden on health, well-being, and productivity.

Definitions of obesity

Commonly used measures for population health

The World Health Organization (WHO) defines obesity as 'abnormal or excessive fat accumulation that may impair health' (WHO 2000). While a number of methods measure an individual's body fat percentage with a high

degree of accuracy, such as doubly labelled water, dual-energy X-ray absorptiometry, and magnetic resonance imaging, the cost of these methods usually prohibits their use in population surveys (Peeters et al. 2016). Instead, such surveys usually rely on anthropometric markers which are simple and reproducible to measure and have a high correlation with percentage body fat. The primary anthropometric measures are weight, height, and waist and hip circumferences. Most commonly, weight and height are recorded and combined to create an index of body mass (the BMI), calculated as weight (in kilograms) divided by the square of height (in metres).

While body mass index (BMI) is valuable for estimating risk of obesity in population groups and for showing trends across time or disparities between groups, BMI alone should not be relied on for diagnostic purposes for individuals: high levels of muscle mass may raise BMI without indicating a risk of excess adiposity, while low levels of muscle mass may put someone at risk of excess adiposity within the 'normal' BMI range.

Adults

Obesity was originally defined by analysis undertaken by the US Metropolitan Life Insurance Company relating BMI values to mortality (James 1976). A BMI of approximately 25 kg/m^2 was identified as the cut-off above which mortality rates increased, with a BMI of 30 kg/m^2 at 20% above this upper 'normal' BMI limit of 25 kg/m^2. In 1995, WHO accepted BMI as the method for assessing degrees of underweight and overweight and took a BMI lower limit of 18.5 kg/m^2 for distinguishing normal from underweight (Table 8.4.1) (WHO 1995).

However, it is recognized that all common epidemiological measures of obesity at a population level have limitations. From a public health perspective, the precise choice of cut-off point is arbitrary: the health hazards are progressive, age dependent, and not substantially changed at any particular cut-off point. The classic comorbidities intrinsically linked to an excess BMI, for example, diabetes, hypertension, gall stones, and coronary heart disease are linearly related to BMI from a BMI nadir of about 19 or 20 kg/m^2.

While anthropometric measures such as weight and height provide simpler, less expensive, assessment of body composition than methods, such as imaging and bioelectrical impedance analysis, they do not provide a direct measure of body fatness, and as such which method is best has been much debated (Tanamas et al. 2016). Furthermore, for the same BMI, Europids generally have

less body fat than Asians, but more than Africans or Pacific Islanders, which has led to suggestions that a lower BMI threshold should be used to define overweight and obesity in Asians, or that further subcategories of BMI should trigger public health action in different populations (WHO Expert Consultation 2004).

Furthermore, as people age, fat mass tends to increase while muscle mass decreases. As a consequence, BMI may remain stable as people age despite an increase in body fat, particularly among the elderly. Sometimes referred to as sarcopenic obesity (Stenholm et al. 2008) the implication is that lower thresholds of BMI should trigger interventions for obesity prevention and treatment in older populations.

Various alternative or additional measures have been advocated to improve estimates of adiposity and/or to provide better prediction of ill-health and risk of chronic diseases. These include waist circumference (WC), waist–hip ratio (WHR), waist-height ratio, neck circumference, conicity index, and body adiposity index. Most of these involve computation of convenience-ratios, which do not correspond to biological interpretation. They are also hard to visualize, a particular obstacle to public understanding in applications for health promotion. Where the range of body fat is very large (as in most population surveys), WC correlates surprisingly strongly with total body fat, explaining 70.4–77.8% of variance, so it is a little better than BMI, at least in men.(Lean et al. 1996) It is also a slightly better predictor of metabolic risk and chronic diseases than BMI, partly by better identifying individuals at increased health risk through greater total body fat, and partly by also including those with central adiposity who are not identified by BMI (Lean et al. 1995). The simplicity of BMI remains its major strength, resulting in recommendation by the WHO that ‘BMI provides the most useful population-level measure of overweight and obesity’ (WHO 2011). However, recent data has indicated that the overlap between those populations categorized as high risk adiposity by WC and BMI are increasingly differing over time, suggesting further consideration may be needed of new, combined measures (Gearon et al. 2018).

Table 8.4.1 provides the international cut-points for BMI and WC in adults. While there are known ethnic differences in level of risk at different cut-points, the WHO recommends all countries report against these cut-points to allow for international comparisons (WHO Expert Consultation 2004).

Table 8.4.1 Body mass index and waist cut-points in adults

	International cut-points*		Additional BMI cut-points for reporting and action
	Waist circumference	BMI	BMI
Underweight		<18.5 kg m^{-2}	<16 kg m^{-2}
			≥16 to <17 kg m^{-2}
			≥17 to <18.5 kg m^{-2}
Normal weight	<80 cm (women)	18.5 to <25 kg m^{-2}	≥18.5 to <23 kg m^{-2}
	<94 cm (men)		≥23 to <25 kg m^{-2}
Overweight	80 to <88 cm (women)	25 to <30 kg m^{-2}	≥25 to <27.5 kg m^{-2}
	94 to <102 cm (men)		≥27.5 to <30 kg m^{-2}
Obese	≥88cm (women)	≥30 kg m^{-2}	
	≥102 cm (men)		
Obese Class I			≥30 to <32.5 kg m^{-2}
			≥32.5 to <35 kg m^{-2}
Obese Class II			≥35 to <37.5 kg m^{-2}
			≥37.5 to <40 kg m^{-2}
Obese Class III			≥40 kg m^{-2}

BMI, body mass index (an indicator of weight for height (kg m^{-2}).

* International cut-points were derived from Europid populations. The WHO recommends use of international cut-points by all countries, and additional use of ethnic-specific cut-points where available.

Source: data from WHO Expert Consultation 2004.

Children

Classifying overweight and obesity in children is more difficult that with adults due to their rapid growth and body changes as they age. Classification systems

based on national population surveys have been developed and are in use in several countries. The International Obesity Task Force (IOTF) published a multinationally based classification system for children in 2000, and extended in 2012, which has been in widespread use since (Cole et al. 2000; Cole and Lobstein 2012). More recently the WHO developed a set of classification standards for children under 5 years, and a further set of classification reference values for older children (WHO 2018c, WHO 2018d). The two international classification systems show broad agreement but the prevalence of overweight and obesity in a given population can differ somewhat according to age and sex across these classification systems. It is recommended that estimates of excess adiposity in child populations should be reported using both IOTF and WHO classification systems to allow backward comparability and estimates of trends.

Obesity as a disease

Over the past five years a number of national medical associations have identified a need to classify obesity as a disease. In the WHO's expert report *Obesity: Preventing and Managing the Global Epidemic* (WHO 2000) obesity is described as a chronic disease, but the description has been challenged, not least because it would classify millions of adults and children as ill. In 2013, the American Medical Association published its support for describing obesity as a disease, arguing that while such a declaration would have no legal implications, it would pave the way for those with obesity to be better treated within the American medical system.

This position statement reflected the growing opinion globally that people with obesity are not receiving the timely, affordable, evidence-based treatment that would improve their health and quality of life. While treatment options and pathways of care exist, it has been shown that many people with obesity do not receive adequate treatment and management due to reasons ranging from discrimination by health professionals to inadequate health system funding (All-Party Parliamentary Group on Obesity 2018).

The rationale for identifying obesity as a disease includes the potential to drive broader healthcare coverage for both the prevention and treatment of obesity, in part through increasing recognition of the biologically irreversible nature of weight gain.

In 2017, the World Obesity Federation released a position statement supporting the identification of obesity as a chronic relapsing progressive disease process (Bray et al. 2017). This position statement argued that 'obesity fits the epidemiological model of a disease process except that the toxic or

pathological agent is food rather than a microbe'. As such they argued for improved treatment and management globally due to the continuous effort needed to control the relapsing disease process of obesity.

At the same time the World Obesity Federation published an accompanying article acknowledging that declaring obesity to be a disease could have a variety of benefits (Lobstein et al. 2017). It argued for the beneficial effects for people living with obesity who require access to medical advice and support, and that declaring obesity a disease would strengthen the argument for dealing with the social determinants, obesogenic environments, and systemic causes of individual weight gain. Furthermore, it may help to counter the commonly held assumption that obesity was a 'lifestyle choice' and entirely an individual's responsibility.

As more health organizations around the world declare obesity as a disease, it will be important to monitor whether this action supports the achievement of better prevention, management, and treatment of overweight and obesity.

Global trends in overweight and obesity

Trends in the prevalence in obesity

As at 2016, some 390 million women and 281 million men were living with obesity globally, and a further 1.3 billion adults were overweight, non-obese (BMI 25–30 kg/m^2) (NCD Risk Factor Collaboration 2017). Among children and youth (ages 5–19y) some 50 million girls and 74 million boys were living with obesity, and a further 213 million overweight, non-obese youth (Box 8.4.1).

Box 8.4.1 Estimates of global obesity prevalence

The figures cited in this chapter are based on the World Health Organization's Global Health Observatory database (see http://www.who.int/gho/ncd/risk_factors/overweight/en/), provided by the NCD Risk Factor Collaboration (see http://ncdrisc.org/index.html). The methods used to make national and regional estimates include interpolations between studies undertaken at different times and cross-matching countries for their demographic similarities. Adjustments are made for survey data which rely on self-reported weights and heights. Classification of BMI in childhood is based on the WHO-recommended cut-offs. Similar methods have been used for the Global Burden of Disease analyses (see http://www.healthdata.org/gbd) although in this case the classification of BMI in childhood is based on the IOTF cut-offs.

When did obesity become a major public health concern? If we look back through the literature we find Kannel and Gordon in the USA (Kannel and Gordon 1974) suggesting in 1974, ‘There is a massive preoccupation with obesity in affluent countries and both the afflicted and their physicians have been engaged in frustrating efforts to correct it’. In the same year, Garrow in the UK (Garrow 1974) stated ‘Obesity is by far the most common and serious nutritional disease in Britain and other affluent societies’.

In that year obesity (as currently defined) was affecting around 13% of the adult population in the USA, and under 7% of adults in the UK. In the next four decades obesity rates in those countries more than trebled, and by 2016 the disease was affecting over 36% of adults in the USA and 28% in the UK, along with 29% in Australia, 27% in South Africa, 29% in Mexico and 35% in Egypt.

These latter two figures are perhaps the most alarming, as the rate of increase in several middle-income economies has been far steeper than that in high-income countries. As Figure 8.4.1 shows (NCD Risk Factor Collaboration 2017) traditionally affluent countries have shown a gradual rise in obesity prevalence from the early 1970s, whereas in several middle-income countries the rise in adult obesity prevalence is more recent, and more dramatic, and is taking place in a context where weight management services may be less accessible and healthcare pathways less developed.

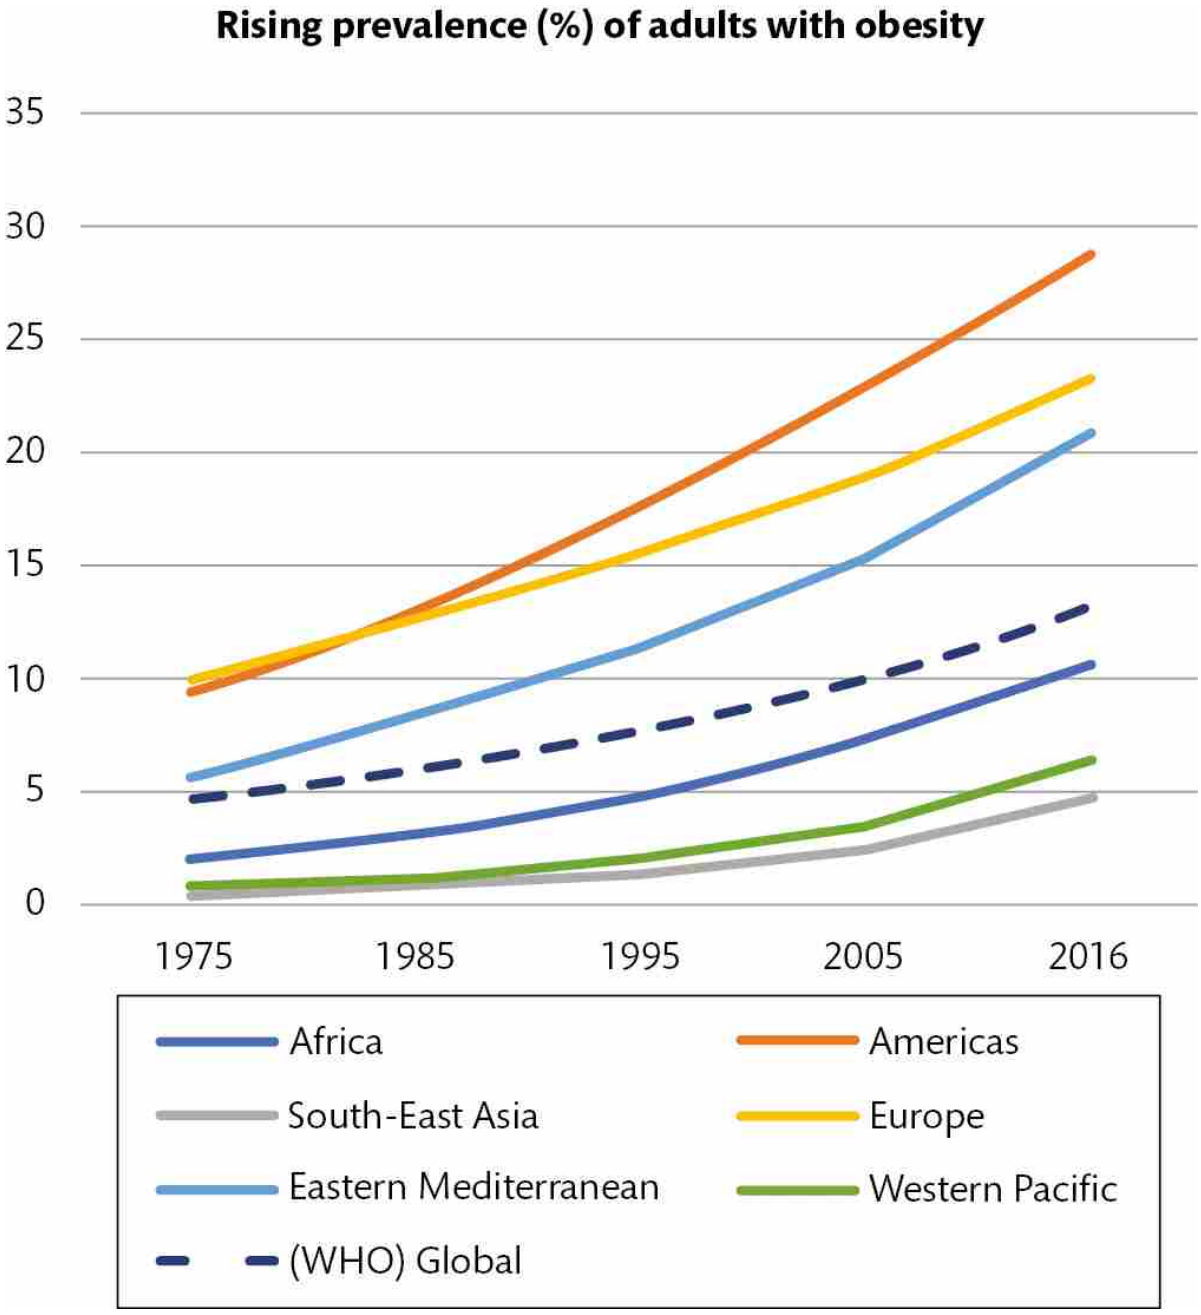

Fig. 8.4.1 Trends in adult obesity prevalence 1975–2016.

As the principle drivers of obesity—including sedentary behaviour, urbanization, and unhealthy and ultraprocessed food consumption—become more globalized, so the rise in obesity prevalence can be seen in populations exposed to these drivers. Estimates undertaken for the Global Burden of

Disease study indicate that in the last decade the countries experiencing the most rapid increase in obesity prevalence are the emerging markets of SE Asia, Latin America, and parts of Africa (Table 8.4.2).

Childhood obesity

Although obesity is still uncommon among children, its prevalence has shown a similar pattern of increase across countries to that of adults (NCD Risk Factor Collaboration 2017) We have noted that there are several methods for defining obesity in children, and while direct comparisons between surveys may not always be robust, trends using the same definitions are strongly indicative of the rising scale of the problem.

As with adults, long-term increases in childhood obesity can be seen for most high-income countries, and more rapid increases found in low- and middle-income economies. Several regions are of particular concern: the countries of Latin America, from Mexico southwards, have shown a doubling of childhood obesity levels in just 20 years, while adolescents in the Middle East from Egypt through to the Gulf are showing obesity prevalence levels around 15–20%, and some Pacific islands are experiencing adolescent obesity prevalence above 30% (Table 8.4.3).

Age and social disparities

While variations in prevalence levels between countries have been high, and can partly be explained by a country's stage of economic development, disparities between population subgroups within countries reveal additional factors of public health concern.

The clearest variation across population group is by age (Fig. 8.4.2). Obesity prevalence increases by age in virtually all countries studied, with a decline in prevalence shown only in the age groups above 65 years in most high-income countries. This accumulation through the life course reflects the difficulty in losing weight once gained, along with the rising prevalence in all age groups from one decade to the next. It means that national averages can mask a more serious crisis: in the UK the average obesity prevalence level is 26% but among

adults aged 55–64y it is 34% (NHS Digital 2017a) and therefore, all else being equal, over a third of adults can expect to become obese during their lives. In the USA the figure for older adults rises above 45% for the general population, and over 57% for non-Hispanic black women.

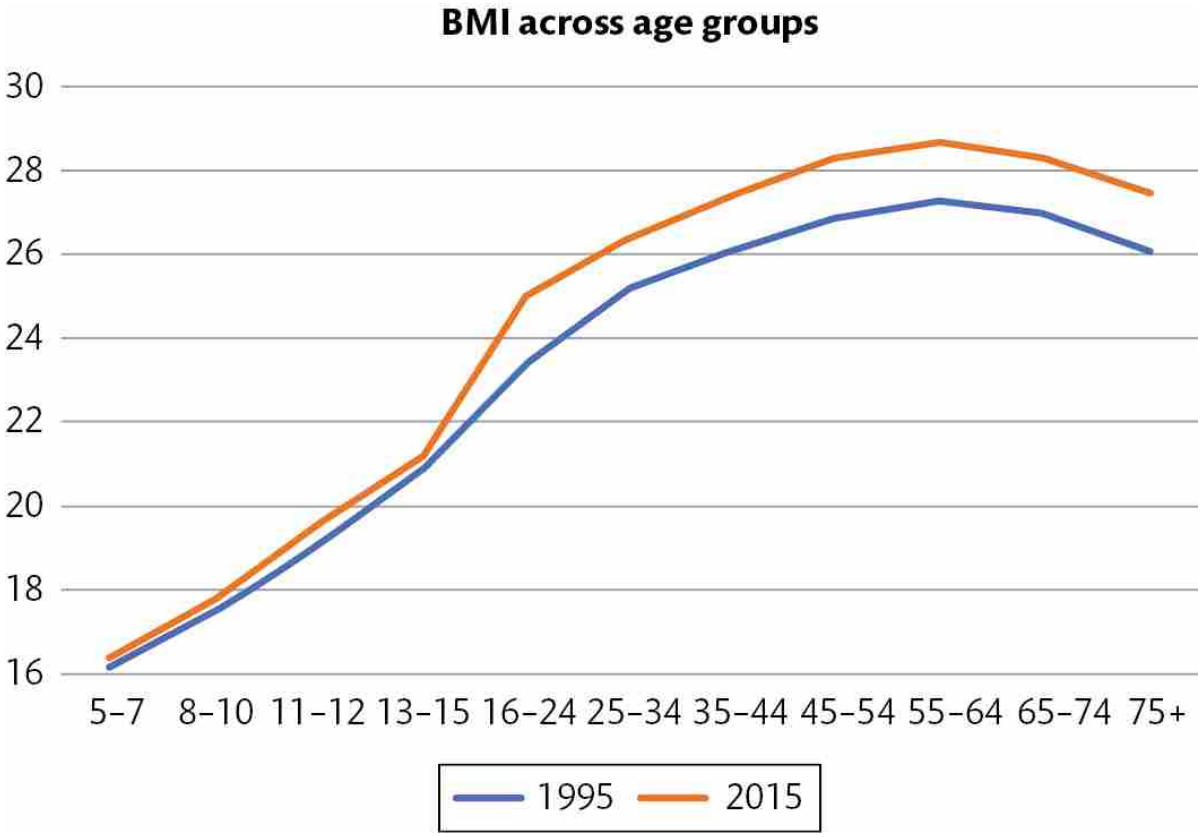

Fig. 8.4.2 Increasing BMI by age to late middle-age in the UK.
Source: data from NHS Digital (2017), 'Health Survey for England 2016: Adult Overweight and Obesity', (London: Health and Social Care Information Centre).

Note that these data reflect cross-sectional surveys in the years shown, and therefore the decline in average BMI after age 60y could be due to several effects apart from an early demise of those people suffering highest levels of overweight. For example, it could reflect the perpetuation of lower BMI among previous generations persisting through each decade, or a specific cohort effect for those who were growing up in the 1920s or 1940s. Equally, it could reflect a significant change in circumstances, for example, moving from earned income to a pension-based income, or to reduced muscle mass rather than reduced

adiposity. The decline applies to both genders, so it is unlikely to be due to a difference in gender survival rates.

Differences in obesity prevalence according to socioeconomic status (measured by level of educational achievement or household income) can be seen in many countries: in high-income countries the risk of developing obesity tends to be higher in less affluent or less educated population groups, with the gradient from highest to lowest socioeconomic (SES) group tending to be most clearly seen for women and for children, and less so for men (McLaren 2007). The data for children are very clearly shown in the UK's National Child Measurement Programme, a survey measuring virtually every child in the country when they enter and leave primary school (aged around 5y and 11y, respectively) (Fig. 8.4.3) (NHS Digital 2017b). Classified by levels of deprivation in the school environs, the data show a clear near-uniform decrease in obesity for each decile decrease in deprivation score.

In low income countries, the gradient tends in the opposite direction, with wealthier or better educated families experiencing a higher risk of developing obesity, possibly in part to their greater exposure to labour-saving, urbanized, processed food environments. This gradient has been shown to reverse as countries progress through the nutrition and epidemiologic transition. The classic papers by Monteiro et al. in 2004 (Monteiro et al. 2004a, 2004b) demonstrate the 'cross-over point' to be at around ($2,500 national per capita GDP at the time).

Other subpopulation groups may show disparities after adjusting for SES. Background racial or ethnic status can determine obesity risk status, and this may interact with gender. In the USA, obesity prevalence is lower for Hispanic males and higher for Hispanic females than it is for the overall population, while for groups of Asian origin prevalence is generally significantly lower than the average, but for black or African-American population groups obesity risk is higher than average for both men and especially women, with the obesity affecting more than 50% of women in this group (Ogden et al. 2014).

Significant disparities are found between ethnic groups in many other countries. In New Zealand, higher than average rates of obesity are found among Maori and especially Pacific Islander groups (Ministry of Health—Manatū Hauora) and the same is the case for Australia's indigenous Aboriginal and Torres Islander peoples (Australian Bureau of Statistics 2018).

While increasing urbanization appears linked to obesity prevalence generally, in some countries—e.g. the USA and Australia—residence in rural or periurban areas confers a greater risk of obesity than residence in inner-urban areas. It is not clear if this holds true after SES differences are taken into account. It should also be noted that there are other population groups likely to be at increased risk of obesity, including recent immigrant populations and refugees dependent on food aid (Grijalva-Eternod et al. 2012; Wandell 2013).

Lastly, nations differ in many respects, but one which opens interesting questions for public health policy is the degree of inequality manifest in a society. Measurements of disparities in wealth, e.g. using the Gini Index, have been found to have a close relationship with various measures of health status in the population, including obesity in adults and children (Pickett et al. 2005; Knai et al. 2012). Thus countries may differ in obesity prevalence in

association with their differences in wealth distribution despite having similar average per capita GDP.

Future prospects

Projecting future prevalence rates from past trends is fraught with difficulty. Past trends differ considerably between countries as we have shown. Changes in prevalence are non-linear, and presumably are self-limiting at some maximum level below 100%, although this may differ between countries and subpopulation groups. Modellers must attempt to distinguish age, cohort, and period effects alongside subgroup differences and changing demographics. While past trends can be helpful to predict future prospects, local and national responses to the obesity crisis may lead to policies which alter the trajectory in one direction, while economic crises, changing market dynamics, trade policies fuel prices, or the impact of global warming on food supplies may alter the trajectories in another.

Despite the problems, some attempt at predicting future trends over the coming decade are helpful, not least for authorities responsible for healthcare services facing rising demand for treatment for the chronically disabling diseases consequent on obesity. Interventions to treat obesity rather than waiting to treat its consequences can be cost-saving, and although guidelines vary between countries, a threshold for intervention most commonly occurs at BMI levels above 35 kg/m^2. Crude projections of the numbers of adults with BMI above 35 kg/m^2 have been made in Table 8.4.4 for some of the world's larger countries.

Table 8.4.4 Top 20 countries for numbers of adults projected to be living with severe obesity (BMI>35kg/m^2)

The social and health costs of overweight and obesity

Language of ‘cost’

Before considering the costs of obesity we need to be clear what we mean. Firstly, there is a move to resist the phrase ‘cost of obesity’ (or ‘burden of obesity’) if it is used in the context of weight-biased language that implies people living with obesity are the cause of social and economic costs to the wider population. In the present discussion we use ‘direct costs of obesity’ to refer to the costs of either treating the disease, or treating the consequences of obesity such as diabetes, liver disease and cardiovascular disease; and ‘indirect costs of obesity’ to refer to the economic losses due to ill-health or premature death. There are also consequential costs to individuals and their families in terms of lost educational opportunity and lowered quality of life.

Adverse health outcomes

Obesity brings a significant change in body function, with alterations in hormonal activity involving insulin, growth hormone, prostaglandins, androgen and oestrogen, and other steroid hormones, changes in joint and muscular physiology, along with raised risks of liver damage, adverse cardiovascular function, poor control of blood sugar and blood lipids, and consequential risk of osteoarthritis, heart disease, stroke, diabetes, liver dysfunction and a range of cancers (WHO 2000).

Additionally, obesity is highly stigmatized in many countries in terms of both the perceived ‘undesirable’ bodily appearance and the apparent character defects it is supposed to indicate, leading to social discrimination. Compared to non-obese peers, people living with obesity are likely to complete fewer years of schooling, are less likely to gain tertiary education and, among women particularly, less likely to enter better-paid employment. Perhaps not surprisingly in these conditions, people living with obesity are more likely to see their own bodies as unattractive and to exclude themselves from social interaction.

Estimated costs and burden of disease

Higher health risks are reflected in greater need for healthcare. Estimates of the relative increase in the need for health services by BMI status have been made in several countries and are shown in Table 8.4.5.

Table 8.4.5 Relative use of health services or expenditure on healthcare

	Australia: use of hospital outpatients (Price Waterhouse Coopers 2015)	Australia: use of hospital inpatients (Price Waterhouse Coopers 2015)	Malta: use of GP services (Price Waterhouse Coopers 2017)	Malta: use of hospital services (Price Waterhouse Coopers 2017)	USA: per capita healthcare expenditure (Arterburn et al. 2005)	Multiple counties: per capita healthcare expenditure (Kent et al. 2017)
BMI 18.5–24.9 Normal weight	1.0	1.0	1.0	1.0	1.0	1.0
BMI 25–29.9 Overweight non-obese	1.14	1.07	1.03–1.15	1.01–1.38	1.099	0.85–1.65
BMI 30–34.9 Obese I	1.25	1.22	1.26–1.38	1.0–1.75	1.231	1.08–1.41
BMI 35–39.9 Obese II	1.39	1.49	1.23–1.57	1.01–1.57	1.448	1.21–1.64
BMI 40+ Obese III	1.07	1.76	1.84–1.85	1.56–4.03	1.815	1.44–2.10

The metrics are not identical across studies, and clearly do not include a number of relevant costs, but the relative increment according to weight status is clear. From these figures, the World Obesity Federation (World Obesity Federation 2017) estimated that the consequential healthcare expenditure resulting from raised body mass in a variety of countries, including those shown in Table 8.4.6.

Table 8.4.6 Examples of estimated healthcare expenditure associated with raised BMI

	2014	2025	2017–2025
United States	$325 bn	$555 bn	$4.2 trn
Egypt	$3.9 bn	$7.8 bn	$58 bn
Australia	$9.0 bn	$17.0 bn	$127 bn
Mexico	$10.2 bn	$20.7 bn	$152 bn
Malta	$115 m	$206 m	$1.6 bn
United Kingdom	$19.1 bn	$30.6 bn	$237 bn
South Africa	$4.4 bn	$8.6 bn	$63 bn
Germany	$31.3 bn	$50.2 bn	$390 bn
Brazil	$16.6 bn	$34.4 bn	$251 bn
Colombia	$2.7 bn	$5.6 bn	$42 bn
Worldwide	**US$600 bn**	**US$1.2 trillion**	**$9.1 trn**

Total (private and government) healthcare expenditure in US$ at 2014 value, adjusted for purchasing power parity, from WHO World Health Report 2014. Projections to 2025 assume World Bank estimates for population growth and linear trends in BMI from 2000–2014 data.

Source: data from World Obesity Federation. Global Data on Costs and Consequences. 2017 Available from: https://www.obesityday.worldobesity.org/ourdata2017

These estimates may prove conservative. An assessment by the Milken Institute in the USA suggested that the direct costs for medical treatment for health conditions causally related to obesity and overweight were valued at US$427.8bn in 2014, or 14% of US healthcare spending (Waters and DeVol 2016).

Besides direct healthcare costs, there are indirect economic costs due to a reduction in economic activity resulting from ill-health attributable to the consequences of obesity. These include costs from absenteeism, presenteeism, and reduced productivity. Examples of these estimates are shown in Table 8.4.7.

Table 8.4.7 Examples of recent estimates of indirect costs associated with obesity

Date	Country	Estimated costs	Basis
2015	Germany	€33.65 bn	Sickness absence, unemployment, nursing care, rehabilitation, early retirement pension, premature mortality, pension for widows and orphans.
2013	Canada	CA$16.4 bn	Unrealised earnings due to poor health and premature mortality (based on the ratio to direct costs).
2012	USA	US$8.65 bn	Loss of productivity due to sickness absence.
2009	Germany	€772 per capita	Loss of productivity due to sickness absence.
2009	Thailand	US$391.8 m	Loss of productivity due to hospital absence and premature mortality.

Sources: data from Tremmel M, Gerdtham UG, Nilsson PM, Saha S. Economic Burden of Obesity: A Systematic Literature Review. Int J Environ Res Public Health 2017; 14. Krueger H, Krueger J, Koot J. Variation across Canada in the economic burden attributable to excess weight, tobacco smoking and physical inactivity. *Can J Public Health* 2015; 106: e171–7.

The Milken Institute report cited here also estimated the indirect costs due to absence or underperformance at work due to ill-health associated with obesity and its consequences, which the Institute estimated at an extraordinary US$988.8bn for 2014. Added to the Institute's estimate of direct costs, the total of $1.4 trillion was equivalent to 8.2% of US gross domestic product for the year.

Other forms of indirect cost have been considered. Additional food has to be grown and transported to meet the needs of heavier populations. Over the three decades 1985–2016 the average adult's BMI in Australia increased by 10.1%, in the UK by 10.4% and in the USA by 12.6%.(NCD Risk Factor Collaboration) Simply to maintain body function at a stable level this implies a 10% increase in food intake for the average adult, implying a significant increase in food supplies beyond that needed for a rise in the numbers of adults. The majority of people do not accumulate excess adiposity until well into adulthood, so it is of concern that for children and adolescents the increases in average BMI over the same period for these three countries were 6.8%, 5.7%, and 8.1%, respectively.

Further costs include the additional costs to infrastructure, both in hospitals and broader industries. A calculation of airline fuel use in the USA suggested that the additional BMI of the USA population in the period 1990–2000 led to a 2.4% increase in fuel requirements for domestic services, or 350m gallons of jet fuel, and added 3.8m tonnes of CO_2 emissions to greenhouse gas emissions (Dannenberg et al. 2004). Calculations have been made for automobile transport in the USA (Jacobson and King 2009) which suggest that in 2008 around 1.1 bn gallons of fuel were used to transport the excess weight of the US population in private vehicles, releasing some 9 m tonnes of CO_2.

The double burden of nutrition

The last century has seen an extraordinary 'nutrition transition' which has led to energy-dense foods and beverages high in sugar and fat becoming widely available to developed and urbanized populations around the globe. A potential double burden of ill-health may occur in populations where the healthfulness of food supplies remains poor: surveys in Vietnam, Brazil, and South Africa have found evidence of overweight children showing lack of growth—stunting—and indeed children in lower-income households in the UK are more likely to be overweight and more likely to be below average height, compared with children in higher-income families (Lobstein et al. 2015).

We are not aware of estimates of the costs of this specific issue. However, there have been recent attempts to estimate the direct and indirect costs for whole populations failing to meet dietary recommendations. A UK study estimated the healthcare costs of poor diets at £5.8 bn for 2006–2007 (Scarborough et al. 2011). An analysis of the economic costs of failing to meet Canadian food recommendations in terms of disease consequences estimated that poor diets were responsible for CA$5.1 bn annually for direct healthcare and CA$8.7bn for indirect costs (Lieffers et al. 2018). This is in addition to the costs associated with overweight and obesity, which have been estimated at CA$23.5 bn annually (Krueger et al. 2015).

Causes of overweight and obesity

A complex system of determinants

For individuals, obesity results from an imbalance between energy intake and expenditure, whereby energy intake is consistently greater than energy

expenditure. Behind this apparently simple equation, obesity is best contextualized as resulting from a complex set of interactions between a wide range of drivers, reflective of the broader socioecological model (Dahlgren and Whitehead 1991; Swinburn et al. 2011; Ohri-Vachaspati et al. 2015).

Obesity results from complex interactions between an individual's physiology, psychology, physical activity, and food consumption, and the social and environmental factors that surround them, including the broader social psychology, the physical activity environment, and food production and trade processes (Vandenbroeck et al. 2007). This complexity was mapped in an obesity system map for the UK Foresight report in 2007 (Vandenbroeck et al. 2007)—which is colloquially referred to as the 'spaghetti map' (Allender et al. 2015) due to the number of interconnections within and across each of the factors (Fig. 8.4.4).

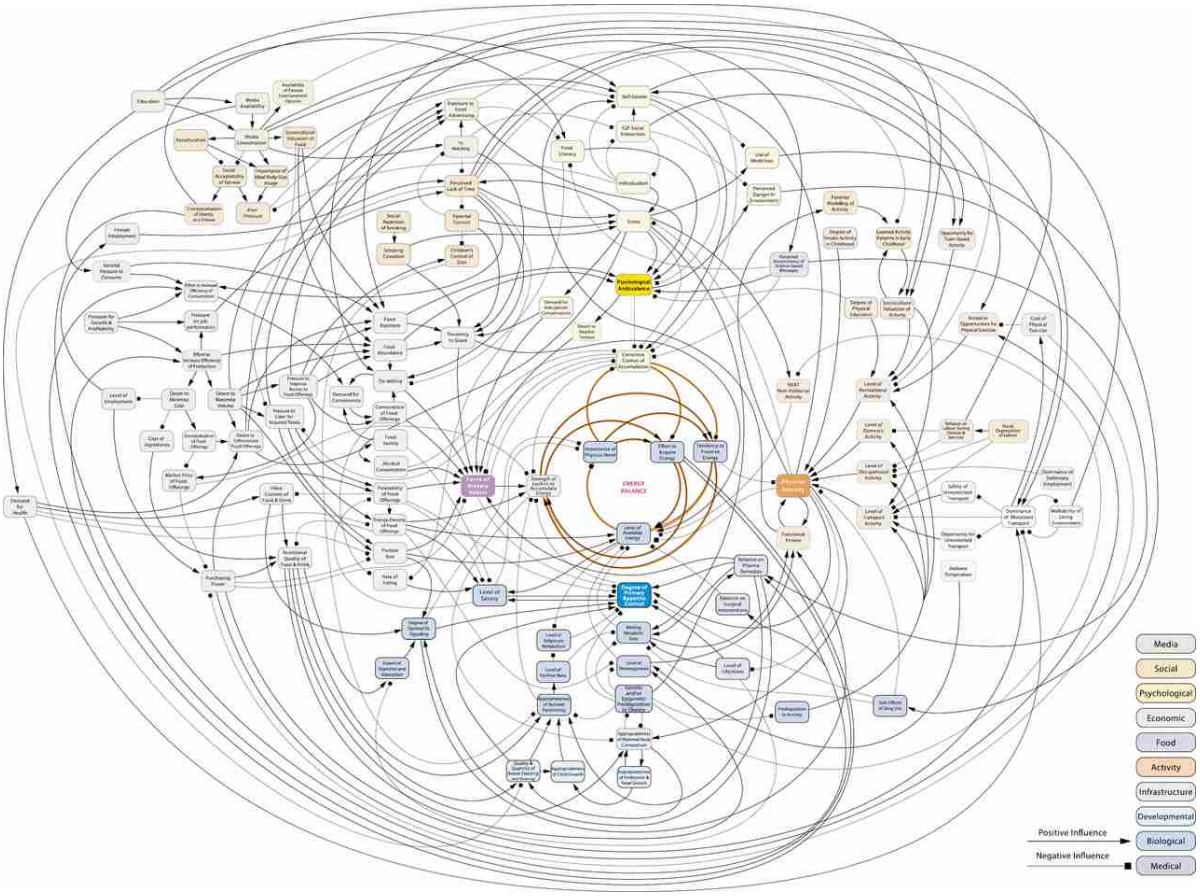

Fig. 8.4.4 The Foresight obesity system map.

Reproduced from Vandenbroeck, IP et. al. (2007), 'Foresight. Tackling Obesities: Future Choices—Obesity System Atlas', (Government Office for Science, UK Government's Foresight Programme) under the Open Government License.

In the centre of these models is the set of individual characteristics such as age, sex, race/ethnicity, and genes that influence an individual's propensity for weight gain. These individual characteristics are then influenced by a range of lifestyle behaviours, including diet, physical activity, and sleep. At the level of social and community networks and environments, influencers include sociocultural, socioeconomic, workplace, recreation, and transport environments, all of which amplify or attenuate the individual level drivers. These in turn are influenced by, and influence, the high-level systemic drivers such as food and transport systems and the broader socioeconomic, commercial, and political determinants of health.

The obesity epidemic

The obesity epidemic, now seen across the world, has resulted from a series of large changes to how we live, including greater urbanization, a food system providing more accessible, affordable, and heavily marketed products and automation leading to decreased activity in our daily lives. While, as indicated earlier, for an individual there are a number of factors contributing directly to the development of obesity at the individual level, the major cause of the global pandemic of obesity is thought to be the global changes in food and diet (Swinburn et al. 2011).

The increases in the prevalence of obesity first seen in high-income countries are now being observed in low- and middle-income countries as they rapidly urbanize and food companies increase their investment in these regions (Friel and Baker 2009; Baker and Friel 2014). China is an illustrative example having recently experienced a transition from a history of undernutrition to a rapid increase in obesity (Gordon-Larsen et al. 2014). Over the past two decades the national health survey in China documents rapid changes in diet, activity, and obesity, all reflective of large social change (Popkin 2014). Through analysis of the China Health and Nutrition Survey, Popkin et al. have documented changes to the food supply, cooking and eating behaviours, transportation modes, and physical activity patterns, all reflective of the tripling in the prevalence of overweight in adults observed between 1991 and 2009 (Popkin 2014).

Globally, these changes to our food and activity environments have been termed the development of ‘obesogenic’ environments (Swinburn et al. 1999) The recognition that our environments encourage and incentivise the very behaviours that contribute to obesity was pivotal in broadening the search for solutions from individual education and behavioural change to transformation of our social, economic, political, food, and physical activity environments.

Causes of causes

As well described by Friel et al. (2007), ‘Focusing only on direct action to make people eat more healthily and be more physically active misses the heart of the problem: the underlying unequal distribution of factors that support the opportunity to be a healthy weight. Unless this oversight is addressed the obesity epidemic and its inequities will persist and possibly increase.’ These causes of causes, or upstream determinants of health, set the context for our obesogenic environments. Housing, income, trade, and societal norms all affect the likelihood of overconsumption and sedentary behaviour.

The policy and economic context strongly influences both the level of growth and consumption, and the resources (social, economic, knowledge, and

skills) that citizens have at their disposal to maintain healthy lifestyles. While direct action will need to be taken at the level of food and activity environments, this will need to include consideration of the upstream 'causes of causes' in order to identify effective and equitable intervention targets.

Diet and physical activity

In 2011 Swinburn et al. postulated a 'tipping point' for the obesity epidemic, identifying diet to be the primary direct driver of current obesity trends (Swinburn et al. 2011). While acknowledging that all the factors identified in the Foresight map contribute both at an individual and societal level to weight gain and obesity, they illustrate that the obesity epidemic since the 1970s can be explained from two distinct phases: 'the so-called move less, stay lean phase (1910–60), characterized by decreasing physical activity levels and energy intake, and a population that remained lean; and the subsequent so-called eat more, gain weight phase, characterized by increasing energy intake and a concomitant rise in population weight' (Swinburn et al. 2011). Here we explore the characteristics of diet and physical activity that have been shown to affect the propensity of an individual, and a population, to gain weight.

The evidence demonstrates that an individual's diet is driven by factors across multiple levels of the socioecological model: the microlevel (interpersonal and intrapersonal factors)—such as an individual's knowledge and skills and their social networks and social norms; the mesolevel (food environment)—such as the marketing of foods and beverages and their perceived and actual availability and affordability; and the macrolevel (broader sociopolitical factors)—such as marketing regulations and agricultural policies (Peeters 2018).

There are many studies demonstrating links between specific foods, nutrients, and dietary patterns and obesity. A review in 2016 by Mozaffarian (Mozaffarian 2016) concludes that robust evidence exists to recommend increased fruits, non-starchy vegetables, nuts, legumes, fish, vegetable oils, yogurt, and minimally processed whole grains; and fewer red meats, processed (e.g. sodium-preserved) meats, and foods rich in refined grains, starch, added sugars, salt, and trans fat, when considering the outcomes of obesity, diabetes, and cardiovascular disease. Further studies have suggested prospective associations between factors including diet quality and weight maintenance (Romaguera et al. 2010; Bertoia et al. 2015; Fung et al. 2015; Schulze et al. 2018) and between soft drink consumption and weight gain (Malik et al. 2006; Malik et al. 2013; Singh et al. 2015; Bucher Della Torre et al. 2016).

Levels of physical activity and sedentary time are similarly driven by factors across multiple levels of the socioecological model: the microlevel (interpersonal and intrapersonal factors)—such as an individual's knowledge and skills, perceptions of safety, and their social networks, and social norms; the mesolevel (physical activity and transport environments)—such as the walkability of a neighbourhood, the availability of public transport and the availability and affordability of physical activities; and the macrolevel (broader sociopolitical factors)—such as urban planning and transport policies (Durand et al. 2011; Hesketh et al. 2017). While there are clear links between activity levels and weight gain for the individual, population studies demonstrate that levels of PA have not changed substantially since the 1980s in many countries (Swinburn et al. 2011; Rodgers et al. 2018).

A number of observational studies and reviews demonstrate the link between the number of hours spent sitting, the number of hours spent watching television, or screens in general, levels of moderate and vigorous physical activity, and transport mode with weight gain and obesity (Dunstan et al. 2005; Turrell et al. 2018).

Genes and biology

The recent World Obesity Federation position statement on obesity articulated a perspective of obesity as a chronic, relapsing disease process. In this process the primary driver of current weight gain, food (particularly foods that are high in energy density such as fat, or in sugar-sweetened beverages), interacts with the other drivers of weight gain, including low physical activity and inadequate sleep, and with the individual's genetic susceptibility.

There are a few known genes with a strong effect on the development of obesity, such as that for leptin, and there are a large number of genes with contributing effects to weight gain susceptibility. In addition to direct genetic effects, we also now know that both epigenetics and the body's weight maintenance physiology play a role in an individual's susceptibility to weight gain and capacity for weight maintenance and weight loss.

In the past decade, our understanding of the role of epigenetics in the development of obesity has increased rapidly (van Dijk et al. 2014). A recent review of studies investigating the association between obesity and either global, site-specific, or genome-wide methylation of DNA has demonstrated that, while there was evidence for a number of obesity-associated differentially methylated sites, there was no consistent evidence for a relationship between global methylation and obesity. Still an emerging field, the current evidence

suggests there are epigenetic modifications *in utero* that may both assist in predicting future obesity risk, and represent modifiable targets to reduce this risk (van Dijk et al. 2014; van Dijk et al. 2015).

For those who attempt weight loss, the physiology of the body is a powerful driver of weight regain. As described in detail by Sumithran et al. (Sumithran and Proietto 2013), in the hypothalamus, hormonal signals from the gastrointestinal tract, adipose tissue, and other peripheral sites are integrated to influence appetite and energy expenditure. In those who lose weight intentionally there are several physiological changes that encourage weight regain, including alterations in energy expenditure, metabolism, and hormone pathways involved in appetite regulation, many of which may persist long term.

Obesity in a 'syndemic' of epidemics

Obesity, together with undernutrition and other dietary risks, are currently by far the largest cause of poor health globally, but are likely to be overtaken by the consequences of climate change. These three pandemics—obesity, undernutrition, and climate change—represent a 'syndemic' or synergy of epidemics because they co-occur in time and place, interact with each other to produce complex sequelae, and share common underlying societal drivers. Although beyond the scope of the present chapter, this global syndemic represents the paramount public health challenge in the twenty-first century. It is discussed in greater detail in the forthcoming report of the Lancet Commission on Obesity (Lancet Commission on Obesity 2019).

Prevention of overweight and obesity

A range of public health strategies are needed to ensure reductions in risk of obesity throughout the life course (Baker et al. 2017). Specifically, strategies are needed to reduce intergenerational transfer and development of susceptibility, to reduce weight gain and support weight maintenance throughout life for those at a healthy weight, to support weight maintenance and moderate weight loss in those with a weight just outside the healthy weight range, and to support weight maintenance after weight loss for those with obesity.

In addition, public health strategies are needed to mitigate the harms of obesity. Specifically, to reduce the stigma associated with obesity (Puhl and Heuer 2010) and to reduce the impact of obesity on people's capacity to lead a

fulfilling life, including opportunities in employment, housing, and marriage (Black et al. 2018). The advantage of a well-constructed, multisectoral, and multifactorial public health approach is that it can address all these issues concurrently.

Current recommendations for a public health approach to obesity

There is currently significant coherence in the recommendations national and internationally for a successful public health approach to obesity. Many of the recommendations fall under the remit of government, but it is clear that to enable the cultural, political, and economic change required for reduced obesity rates into the future, action is required from the full range of societal stakeholders, from citizens through community and non-government organizations to the private sector (Huang et al. 2015). In addition, it is clear that there is a role for multiple levels of government, from local through state to national governments, as well as multiple sectors of government (Sacks et al. 2009).

Whether the recommendations focus on childhood or whole of society it is clear that we need to enact a range of levers to re-orient our food and activity environments, empower and upskill our citizens, and rethink our societal conversations about obesity (Fig. 8.4.5) (Moodie 2008; McGuire 2012; Commission on Ending Childhood Obesity 2017; WHO 2017b, 2018c). In 2012 WHO set a target of reducing premature mortality from non-communicable diseases by 25% by the year 2025 and for there to be no increase in adult and adolescent overweight and obesity (WHO 2013) In 2017, this was followed by a report from the Commission on Ending Childhood Obesity including the high-level policy actions governments will need to take to achieve this latter target (Commission on Ending Childhood Obesity 2017). WHO has also developed recommendations for action for the private sector (WHO 2004).

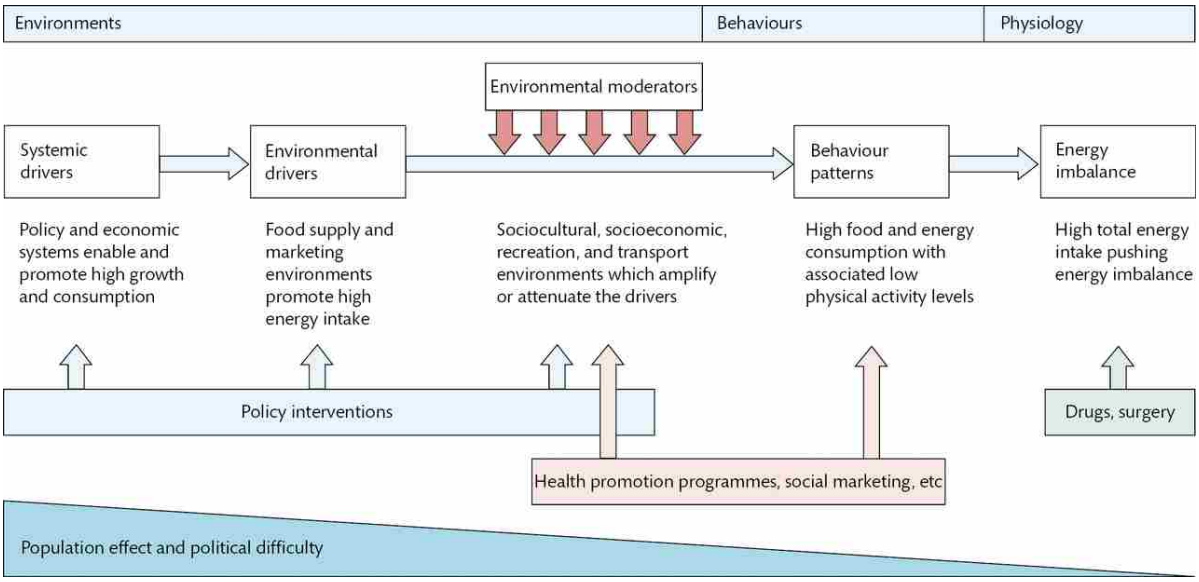

Fig. 8.4.5 A framework to categorize obesity determinants and solutions.

The government recommendations identified by the WHO as the best buys to reduce unhealthy diets and increase physical activity span the key public health levers from pricing, through labelling and guidelines to public education campaigns (Box 8.4.2). Obesity prevention is likely to require government intervention in further areas, such as international trade and food procurement policies (Friel et al. 2013; Hawkes et al. 2013) and is likely to require development of national nutrition, physical activity, and/or obesity plans (Commission on Ending Childhood Obesity 2017; Peeters 2018; WHO 2018c, d) accompanied by ongoing community consultation, research and monitoring (Swinburn et al. 2013).

Box 8.4.2 Key elements of a public health approach to obesity by government

Reduce unhealthy diet

- Implement the global strategy on diet, physical activity, and health
- Implement the WHO recommendations on the marketing of foods and non-alcoholic beverages to children
- Reduce sugar consumption through effective taxation on sugar-sweetened beverages
- Promote and support exclusive breastfeeding for the first 6 months of life, including promotion of breastfeeding
- Implement subsidies to increase the intake of fruits and vegetables
- Limiting portion and package size to reduce energy intake and the risk of overweight/obesity
- Implement nutrition education and counselling in different settings (e.g. in preschools, schools, workplaces, and hospitals) to increase the intake of fruits and vegetables
- Implement nutrition labelling to reduce total energy intake (kcal), sugars, sodium, and fats
- Implement mass media campaign on healthy diets, including social marketing to reduce the intake of total fat, saturated fats, sugars, and salt, and promote the intake of fruits and vegetables

Reduce physical inactivity

- Implement the global strategy on diet, physical activity, and health
- Implement community-wide public education and awareness campaign for physical activity which includes a mass media campaign combined with other community-based education, motivational and environmental programmes aimed at supporting behavioural change of physical activity levels
- Provide physical activity counselling and referral as part of routine primary healthcare services through the use of a brief intervention
- Ensure that macrolevel urban design incorporates the core elements of residential density, connected street networks that include sidewalks, easy access to a diversity of destinations and access to public transport
- Implement a whole-of-school programme that includes quality physical education, availability of adequate facilities and programmes to support physical activity for all children
- Provide convenient and safe access to quality public open space and adequate infrastructure to support walking and cycling
- Implement multicomponent workplace physical activity programmes
- Promotion of physical activity through organized sport groups and clubs, programmes, and events

Source: data from World Health Organization. (2017). Tackling NCDs: ‘best buys’ and other recommended interventions for the prevention and control of noncommunicable diseases. World Health Organization. https://apps.who.int/iris/handle/10665/259232.

A number of international bodies have also provided detailed recommendations to improve population diets and physical activity levels. The World Cancer Research Fund, International hosts the NOURISHING framework (Hawkes et al. 2013). This framework summarizes the policy domains required to improve population diets and an accompanying database collates information about implemented polices to promote healthy diets and reduce obesity. WHO’s Global database on the Implementation of Nutrition Action (GINA) serves a similar purpose, including how programmes are implemented, country adaptations, and lessons learnt (WHO 2018a). The Global Physical Activity Network hosts a knowledge database focusing on

physical activity policies and including summaries of related evidence and implementation (WHO 2018b).

Further, to see such recommendations enacted there will need to be an increase in the political and societal will for action (Huang et al. 2015; Baker et al. 2017). A recent review by Baker and colleagues (Baker et al. 2017) posits that it is possible to build and galvanize political commitment to obesity prevention. They identify a significant role for public health professionals in this process, suggesting that the catalysts will include 'strategic actions by cohesive, resourced and strongly led nutrition actor networks' (Baker et al. 2017). Such actions can be supported by evidence that supports a political ideology and feasible policy options (Clarke et al. 2016). Successful implementation of recommendations will also require a response to the substantial industry opposition to many of the recommended policies. For the first time the Director General of the WHO spoke about the critical role of regulation to contain the food and drink industries, stating 'it is not just Big Tobacco anymore. Public health must also contend with Big Food, Big Soda, and Big Alcohol. All of these industries fear regulation, and protect themselves by using the same tactics' (Chan 10 June 2013). One consequence of this recognition is the development of strong and transparent conflict of interest guidance documents (Buse et al. 2017; WHO 2017a).

Finally, it is important to recognize that while a public health approach to obesity is urgently needed, without an integrated and concurrent focus on greater accessibility and availability of appropriate treatment options, the burden of obesity will continue for many decades.

Evidence of impact

Many of the proposed population obesity prevention strategies have been implemented, evaluated, and modelled for population impact and cost-effectiveness. Comparative cost-effectiveness analyses have demonstrated that some of the regulatory population approaches, including a sugary drinks tax, restricting marketing of unhealthy food and drink and increasing availability of healthy food options relative to unhealthy food options, are likely to be cost-saving at a societal level, leading to reductions in obesity and its sequelae over the lifetime (Table 8.4.8) (Gortmaker et al. 1993; Carter et al. 2009; Vos et al. 2010; Dobbs et al. 2014). Large population benefit has also been identified as a consequence of strategies that change the behavioural defaults, such as food reformulation and decreases in standard portion sizes.

Table 8.4.8 Cost-effectiveness of population obesity prevention interventions

Intervention	Cost-effectiveness*	Other information
Portion size control	Cost-effective	High population impact Evidence of behaviour change
Reformulation	Cost-effective	High population impact Limited evidence for behaviour change
School curriculum	Cost-effective	High population impact Evidence of behaviour change
Labelling	Cost-effective	Moderate population impact Limited evidence for behaviour change
Price promotions	Cost-effective	Moderate population impact Logic model of behaviour change
Marketing restrictions	Cost-effective	Moderate population impact Limited evidence for behaviour change
Tax on high sugar high fat products	Cost-effective	Moderate population impact Logic model of behaviour change
Public health campaigns	Cost-effective	Low population impact Logic model of behaviour change

* Not cost-effective >=$USD50,000/DALY saved; Cost-effective <$USD50,000/ DALY saved; Cost-saving

Note: all analyses done in the context of the United Kingdom.

The impact of a population strategy to improve one element of the food or activity pathways currently driving obesity will necessarily take a number of years to effect weight gain and obesity. In addition, the effect of any given pathway may be difficult to identify among the range of societal changes affecting obesity. In order to support evidence-based decision making it will be important to ensure the full range of evidence is collected and integrated. Approaches integrating logic pathways and systems dynamics will facilitate conclusions on whether a given policy, intervention, or programme is having its intended effect on the direct target behaviours, any unintended effects, and eventually its intended effect on weight gain and obesity (Peeters 2018). Recent evaluations have begun to adapt approaches from systems science (Rutter et al.

2017; Owen et al. 2018). While these methods are still evolving, by identifying and integrating a variety of evidence sources, such approaches have the potential to provide a more comprehensive evaluation of obesity prevention policies.

One approach that has underpinned a number of intervention evaluations has been the quantification of the effect of energy imbalance on bodyweight by Hall and colleagues (Hall et al. 2011). This mathematical modelling approach simulates energy expenditure adaptations during weight loss using findings from human metabolism studies. In addition to informing multiple modelling studies, this approach identified an important characteristic of the obesity epidemic: that a very small average daily energy imbalance between intake and expenditure of about 30 kJ per day can explain the observed average weight gain. This is equivalent to less than a biscuit a day, demonstrating the potential of effective prevention strategies to impact on population obesity rates.

For long-term impact, implemented policies and programmes will need not only to be effective, but also to be sustained and to be equitable. Recent analyses of population obesity trends have shown no reduction in inequalities in obesity in high-income countries (Devaux and Sassi 2013; Chung et al. 2016). Further, there is some evidence that while obesity rates may be improving in some population groups, these improvements are occurring more often in less disadvantaged groups than more disadvantaged groups (Chung et al. 2016). To ensure that implemented policies benefit the most disadvantaged citizens, who are also likely to carry the highest burden of risk, a more comprehensive understanding of differential effectiveness across different population groups is required. A selection of population obesity prevention policies have been evaluated for such differential effectiveness, demonstrating that a sugary drinks tax and whole of community interventions are likely to be effective across the socioeconomic spectrum. However, the majority of recommended policies have not been evaluated for the equity impact. It will be important to continue to build evaluations of the equity effect of such policies (Backholer et al. 2014; Peeters and Backholer 2015). It will also be critical to continue to build the evidence regarding synergistic effects with other related and substantial population issues, including undernutrition climate change (Lancet Commission on Obesity 2019).

Conclusions

A successful public health approach to obesity will require strong political commitment and leadership, accompanied by community and organizational support. Re-orienting our food and physical activity environments alongside supporting and upskilling our citizens will drive the culture change required to reverse the obesity epidemic. A comprehensive, integrated multisectoral approach will be required to reduce intergenerational transfer and excess weight gain, as well as to support weight maintenance in those who have experienced intentional weight loss. Evaluation techniques will need to continue to evolve to ensure implemented interventions are effective, equitable, and sustainable.

8.5

Physical activity and public health

Nyssa T. Hadgraft, Neville Owen, and Paddy C. Dempsey

Introduction

Physical activity has well-established health benefits. However, large proportions of the adult populations of developed countries, and rapidly urbanizing developing countries are insufficiently physically active for health benefits. Additionally, many people's lives are characterized by large amounts of time spent sitting. This represents a formidable set of public health challenges.

Although the relationships of exercise and physical activity with health have been topics of interest for millennia (Tipton 2014; Myers et al. 2015), the modern era of physical activity and public health arguably dates back to the early 1950s with the seminal epidemiological studies of Morris and colleagues. These involved employees of the London Transport Executive (bus drivers compared to conductors) and Post Office (civil servants compared to postal workers). The main findings were that the largely sedentary bus drivers had almost double the age-adjusted rate of fatal coronary heart disease, when compared with conductors who spent much of their workday climbing stairs, walking, and standing. Similarly, the incidence of coronary heart disease was lower in the active postal workers compared to sedentary civil service clerks and executives (Morris et al. 1966, 1953). From a broader public health perspective, it is interesting to note that one of the initial hypotheses considered by Morris and colleagues was the potential effects of stress on the cardiovascular health of bus drivers, whom it would be assumed would be more socially isolated in their jobs than would the conductors.

Some 70 years on from the Morris studies, residents of developed and developing countries have been subject to a broad set of demographic,

epidemiological, economic, social, and technological transitions. Widespread urbanization, particularly in low- and middle-income countries, has meant large segments of traditionally rural populations are moving into cities. Many previously manual tasks in the occupational and household sectors have become automated, making life easier and safer in many respects. A pervasive consequence of these changes is that the living environments of large numbers of people globally are becoming less supportive of structured and incidental physical activity, and more conducive to large amounts of time spent sitting. For this reason, physical inactivity has been called a 'global pandemic' (Kohl et al. 2012); one requiring multidisciplinary and multisectoral approaches (Reis et al. 2016).

In this chapter, we focus on physical activity and sedentary behaviour (put simply, too little exercise and too much sitting), in the contemporary public health context, highlighting:

the key definitions and distinctions around physical activity, exercise, and sedentary behaviour
current evidence on relationships with health outcomes, and current physical activity recommendations
current evidence on prevalence and trends in physical activity and sedentary behaviour, and some of the key issues for surveillance and measurement
how physical activity and sedentary behaviour may be understood in ways that will inform public health approaches

We emphasize the importance of an interdisciplinary and intersectoral strategy—working with constituencies beyond the public health field, such as urban planners, architects, and policymakers, in order to create activity-friendly built environments that provide socially equitable opportunities for physical activity to be part of everyday living.

Physical activity and sedentary behaviour: definitions, health consequences, and guidelines

Definitions

When thinking about what constitutes physical activity and where it takes place, images that might come to mind are people working out in a gym, or

playing sport. However, physical activity is broader than structured exercise. Although often used interchangeably, ‘physical activity’, ‘exercise’, ‘physical fitness’, and ‘sedentary behaviour’ are terms that describe related but distinct concepts. Clear definitions and distinctions are important for research and practice in this field (see Table 8.5.1) (Caspersen et al. 1985; Pate et al. 2008; Brown et al. 2012; Tremblay et al. 2017).

Table 8.5.1 Key terms and definitions: physical activity and sedentary behaviour

Physical activity	Any bodily movement produced by skeletal muscles that expends energy. The term ‘physical activity’ usually refers to the subset of activity that produces substantial health benefits—e.g. moderate-intensity to vigorous intensity activity in bouts of at least 10 minutes at a time. This can be from leisure-time physical activity, transportation (e.g. walking or cycling), occupational or household work, play, games, sports, or planned exercise.
Exercise	A*subset* of physical activity that is purposeful, planned, and structured—with an objective more geared towards improving facets of physical fitness (see next); the term ‘exercise’ is at times used synonymously with ‘physical activity’.
Physical fitness	A set of attributes that people have or achieve that are health or skill-related, such as cardiorespiratory endurance, muscular strength and endurance, flexibility, balance, and body composition. The degree to which people have these attributes can be measured with specific tests.
Baseline activity	All light-intensity activities of daily life, such as standing, walking slowly, and lifting light weight objects. It may also include short episodes of moderate or vigorous activity, such as climbing a few flights of stairs.
Sedentary behaviours	Any waking behaviour characterized by an energy expenditure ≤1.5 metabolic equivalents (METs), while in a sitting, reclining, or lying posture. Note that this is different from ‘physical inactivity’ (see earlier).

As noted earlier, there is now increased interest in the distinct health effects and determinants of sedentary behaviour—sitting. While ‘sedentary’ was often historically used to describe someone who did not engage in sufficient physical activity (i.e. physically inactive), more recently it has been specifically defined to refer to *any waking behaviour characterized by an energy expenditure ≤1.5 metabolic equivalents (METs), while in a sitting, reclining or lying posture* (Sedentary Behavior Research Network 2012; Tremblay et al. 2017).

Physical activity and exercise can be quantified using the constructs of *intensity* (how hard?), *duration* (how long?), *frequency* (how often?), and *mode* (what type?), for example, walking, running, swimming, cycling, etc. (Powell et al. 2004). These constructs are used to determine whether someone meets physical activity guidelines (see Box 8.5.2).

Health consequences: why physical inactivity and sedentary behaviour are crucial public health issues

Strong evidence demonstrates that physical inactivity is a modifiable risk factor for a wide spectrum of health conditions, including non-communicable diseases that are a rapidly growing public health concern in developed and developing countries. It has been estimated that 6–10% of all deaths from non-communicable diseases (including 7% of deaths associated with type 2 diabetes, 6% of coronary heart disease deaths, and 10% of breast/colon cancer deaths) worldwide can be attributed to physical inactivity, making it the fourth leading cause of death worldwide (Lee et al. 2012).

Physical inactivity is related not only to increased risk of illness and premature mortality, it also results in a substantial economic burden worldwide. In the first global estimate for the economic burden of physical inactivity (based on data from 142 countries, representing 93.2% of the world's population), it was conservatively estimated that the effect of physical inactivity cost the world economy more than $67.5 billion through healthcare expenditure and productivity losses in 2013. Low- and middle-income countries had the largest disease burden from physical inactivity (Ding et al. 2016).

There are numerous benefits to health from physical activity; including reducing the risk of excessive weight gain, type 2 diabetes, injurious falls, depression, and loss of cognitive function (Warburton et al. 2010; WHO 2010; Warburton and Bredin 2016; Physical Activity Guidelines Advisory Committee 2018); see Box 8.5.1).

There is also moderately strong evidence that physical activity maintains functional ability in older adults, helps maintain weight loss, improves sleep quality, and reduces the risk of hip fracture and osteoporosis.

Different types of physical activity acting through multiple physiological pathways influence a broad array of health outcomes. The acute and chronic

physiological adaptations that can lead to ill-health largely depend on the type of activity performed. For example, aerobic activities tend to cause many changes to the heart and vascular system (e.g. increased stroke volume, increased capillary density, reduced peripheral resistance). Resistance activities (e.g. weight training or working against body weight) have modest effects on the cardiovascular system, but do improve muscle strength and endurance (Powell et al. 2004; Garber et al. 2011). This highlights that any single activity is unlikely to be optimal for comprehensive health benefits and will depend upon the health outcome of most interest to the population subgroup of concern.

At the lower end of the activity spectrum, accumulating research also indicates that reducing and replacing sedentary behaviours with light-intensity activities is beneficial in a variety of populations, on a smaller scale, for metabolic and cardiovascular health outcomes (Dempsey et al. 2016; Chastin et al. 2017; Chastin et al. 2018). Consistent evidence from prospective observational studies across numerous countries now also indicates that excessive sedentary behaviour (sitting) is also associated with an increased risk for all-cause mortality, heart disease, diabetes and some cancers (Wilmot et al. 2012; Biswas et al. 2015), and may be further exacerbated in those who are insufficiently active or unfit (Biswas et al. 2015; Bouchard et al. 2015; Ekelund et al. 2016). A recent meta-analysis (Chau et al. 2013) estimated that some 6% of all deaths could be attributed to daily self-reported sitting time.

Since much of the world's population is physically inactive (Hallal et al. 2012), and time spent sedentary (with a high proportion of that time spent in sitting in prolonged bouts) accounts for a majority of adults' waking hours (Matthews et al. 2008; Healy et al. 2015), many of the aforementioned figures are likely underestimating the global economic and disease burden associated with physical inactivity and excessive sitting time. From a public health perspective, whether there is a minimum volume of physical activity that may reduce some of the health risks associated with prolonged sitting, or a threshold above which the benefits of physical activity are attenuated, is a topic of contemporary research interest (Powell et al. 2004).

Box 8.5.1 Strength of the evidence on the health benefits of physical activity

Strong evidence of reduced rates of:

- all-cause mortality
- coronary heart disease
- high blood pressure
- stroke
- metabolic syndrome
- type 2 diabetes
- breast cancer
- colon cancer
- depression
- falling

Strong evidence of:

- increased cardiorespiratory and muscular fitness
- healthier body mass and composition
- improved bone health
- increased functional health
- improved cognitive function

Moderately strong evidence that physical activity:

- helps maintain functional ability in older adults, helps maintain weight loss, improves sleep quality, and reduces the risk of hip fracture and osteoporosis

Physical activity and sedentary behaviour guidelines

Evidence supporting the importance of physical activity for population health may be found in a number of landmark documents, including:

the 1996 US Department of Health and Human Services' *Surgeon General's Report on Physical Activity and Health* (US Department of Health and Human Services 1996)
the 2008 US Department of Health and Human Services *Physical Activity Guidelines for Americans* (US Department of Health and Human Services 2008; Physical Activity Guidelines Advisory Committee 2018)
the 2010 World Health Organization (WHO) *Global Recommendations on Physical Activity for Health* (WHO 2010)
and, in 2010, the *Toronto Charter for Physical Activity* was ratified at the 3rd International Congress for Physical Activity and Health (Bull et al. 2010), calling for global action to prioritize physical activity for all.

Based on extensive evidence syntheses and reviews compiled by national and international bodies, there have been generally consistent recommendations developed in relation to adults' physical activity. The WHO's recommendations for adults aged 18–64 are to perform at least 150 min/week of moderate-intensity aerobic physical activity (e.g. brisk walking, gentle bicycling), or at least 75 min/week of vigorous intensity aerobic physical activity (e.g. jogging, running, hard bicycling), or an equivalent combination of moderate and vigorous. In addition, it is recommended that individuals should engage in muscle-strengthening activities at least 2 days/week (see Box 8.5.2) (WHO 2010). More than the suggested minimum total of 150 min/week of activities (up to 300 min/week are suggested) is likely to provide additional benefits. The WHO recommendations were developed with the goal of primary prevention of non-communicable diseases (Vuori 2018).

For those who are inactive or highly sedentary, any physical activity is beneficial. There are health benefits from volumes of physical activity less than half the recommended amount (Powell et al. 2004; WHO 2010). Indeed, a curvilinear reduction in risk occurs for a variety of diseases and conditions across volume of activity, with the greatest improvements in health and mortality risk tending to occur when those who are very inactive/sedentary become more physically active (Powell et al. 2004; Haskell et al. 2007; Garber et al. 2011).

Recommendations for older adults (aged 65 or over) are generally the same as for adults, as much as abilities allow, with particular emphasis of avoiding excessive inactivity and sedentary time. For children/adolescents, the recommended amount of moderate-vigorous physical activity is at least

60 min/day, with muscle/bone strengthening exercises recommended at least three times per week.

Recommendations on sedentary behaviour have recently been introduced into some country-specific guidelines, but are less specific than are those for physical activity. For example, Australia's *Physical Activity and Sedentary Behaviour Guidelines* recommend that adults 'minimise the amount of time spent in prolonged sitting' and 'break up long periods of sitting as often as possible' (DoH 2017).

Box 8.5.2 Recommended guidelines for physical activity and sedentary behaviour

- Adults should accumulate at least 150 minutes of moderate-intensity physical activity, or at least 75 minutes of vigorous intensity physical activity throughout the week, or an equivalent combination of moderate and vigorous intensity activity (e.g. running, brisk walking, bicycling, playing tennis, dancing, and swimming).
- For additional health benefits, adults should increase their moderate-intensity physical activity to 300 minutes per week, or equivalent.
- Muscle-strengthening activities involving major muscle groups should be done on 2 or more days a week, e.g. weight training, calisthenics (body weight resistance such as half-squats, push ups, pull ups, sit ups), carrying heavier loads, heavy gardening (such as lifting, digging, or shovelling).
- Avoid inactivity and minimise the total amount of time that is spent sitting, particularly in sitting prolonged bouts; e.g. replace prolonged periods (~30–60 minutes) of sitting (e.g. at work, watching television) with more standing and more incidental activity.

The WHO has provided leadership in recent decades in advocating for action on physical inactivity by member states (Vuori 2018). The *WHO Global Action Plan for the Prevention and Control of Non-Communicable Diseases 2013–2020*, endorsed by the World Health Assembly in 2013, identifies physical inactivity as one of four risk factors for non-communicable diseases, alongside tobacco use, alcohol consumption and unhealthy diets (WHO 2013). In 2018, WHO launched the *Global Action Plan on Physical Activity 2018–2030: More Active People for a Healthier World*, which aims to provide countries with up-to-date guidance on physical activity and a framework for policy responses (WHO 2018). The plan sets a target of a 15% relative reduction in the prevalence of physical inactivity in adults and adolescents by 2030 (WHO 2018).

Physical activity and sedentary behaviour: prevalence and trends

Physical activity

Country comparisons provide insight into variations in physical activity and sedentary behaviour across the world. When assessing self-reported physical activity against the guidelines outlined earlier, the proportion of adults globally who are not meeting guidelines has been estimated at 31.1%. However, country- and region-specific averages vary substantially. For example, only 4.7% of the population are considered inactive in Bangladesh, through to a high of 71.9% in Malta (Hallal et al. 2012). Higher levels of inactivity have been found in the eastern Mediterranean region (43.2%) and the Americas (43.3%), compared to Southeast Asia (17.0%) and Africa (27.5%) (Hallal et al. 2012). In general, higher levels of inactivity are found in higher-income compared to lower-income countries (Dumith et al. 2011). It has been suggested that this may be because the contribution of physical activity from work tends to be lower in higher-income countries (Hallal et al. 2012).

Within individual countries, average physical activity levels also vary across subpopulations—differences that have implications for health inequities and developing appropriately targeted health promotion programmes. One contributing factor may be that safe and affordable spaces to be physically active are less accessible to some population groups, including those of low socioeconomic position, those with disabilities, and girls, women, and older adults (WHO 2018).

Gender differences in physical activity levels have been observed across most countries, with women more likely to be physically inactive than men (Hallal et al. 2012; Bauman et al. 2009, 2012). These differences can be attributed to a range of economic, social, and cultural factors. Women often spend more time in household activities, which are not always captured by physical activity questionnaires (Hallal et al. 2003). However, women across the world also tend to have lower levels of leisure-time physical activity than men (Brown et al. 2016). This may be due to social and cultural factors, such as in countries where women's participation in physical activity can be restricted (e.g. those in the Gulf Cooperation Council) (Mabry et al. 2010). However, gender differences also exist in high-income countries where

cultural barriers to participation are less apparent, suggesting that social norms may also play a role. For this reason, gender-specific strategies may be needed to address the physical activity gap (Brown et al. 2016).

Physical activity levels also appear to vary by socioeconomic status. Leisure-related physical activity levels tend to be greater among those in higher socioeconomic positions, while occupational physical activity is higher for those with a lower socioeconomic position (Gidlow et al. 2006; Beenackers et al. 2012). There is some evidence to suggest that occupational physical activity (which often involves heavy lifting and prolonged, static postures) may not be as beneficial for improving health outcomes as volitional physical activity performed during leisure (Holtermann et al. 2012; Coenen et al. 2018), which has been suggested as a possible pathway through which health inequities manifest (Coenen et al. 2018). This emphasizes the need to consider the *mode* and *setting* when assessing population levels of physical activity and designing interventions, as discussed later in this chapter.

Sedentary behaviour

Recent findings highlight the extent to which adults around the world engage in high volumes of sitting time, but less is known about international prevalence of sedentary behaviour, relative to what is known about physical activity. Cross-country studies have found that self-reported daily sitting time can range from 2.5 to 3 hours per day in countries such as Portugal, Brazil, and Columbia, through to 6 hours/day in Denmark and the Netherlands, and seven hours/day in Japan and Saudi Arabia (Bauman et al. 2011; Loyen et al. 2016). However, data obtained from studies using accelerometers (a type of activity monitor) suggest that these self-report figures may be underestimates of actual time spent in sedentary behaviour, with some reporting adults spend 55–70% of their waking hours engaged in sedentary behaviours (Matthews et al. 2008; Hagstromer et al. 2010) or over 8 hours/day (Bauman et al. 2018).

Physical activity and sedentary behaviour trends

Evidence from high-income countries suggest that the direction of physical activity trends over time vary depending on the setting in which the activity

is being assessed. While leisure-related physical activity levels have tended to remain steady or slightly increased over time, physical activity during work, the domestic environment and transportation has decreased in recent decades (Hallal et al. 2012; Ng and Popkin 2012). Across the globe, fewer people now work in occupations that require them to be physically active (Ng and Popkin 2012). In the United States, the proportion of workers in manufacturing jobs has declined sharply over the last 50 years, while service-related jobs have become more prevalent. In 2008, only 20% of occupations required at least moderate intensity physical activity, down from 48% in 1960 (Church et al. 2011). Many adults now work in desk-based occupations, where over two-thirds of the workday can be spent sitting (Clemes et al. 2014; van Dommelen et al. 2016). Figure 8.5.1, adapted from Ng and Popkin (Ng and Popkin 2012) provides compelling estimates of past, recent, and projected trends across domains of physical activity and sedentary behaviour.

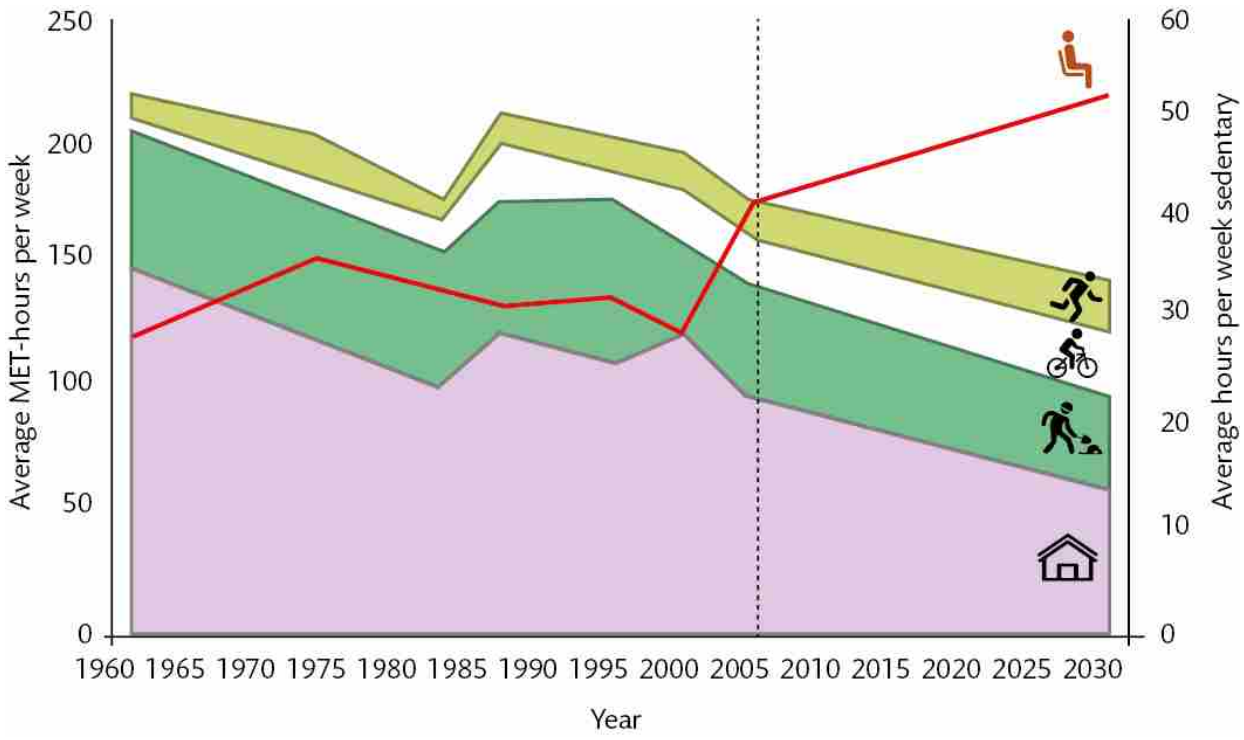

Fig. 8.5.1 UK adults' metabolic equivalents of task (MET)-hours per week of time in sedentary behaviour, and hours per week of all physical activity in different domains (active-leisure, travel, occupational and domestic physical activity): based on time-use surveys measured for 1961–2005 and forecasted for 2006–2030.

Reproduced from Ng SW, Popkin BM. Time use and physical activity: a shift away from movement across the globe. *Obes Rev*. 2012;13(8):659–80, with permission from John Wiley and Sons.

While much of the evidence on physical activity trends has come from high-income countries evidence from China and Brazil suggests that these countries have also experienced reductions in occupational and domestic physical activity in recent decades (Ng and Popkin 2012; Ng et al. 2014). For example, national surveys in China reveal that physical activity levels dropped by 32% between 1991 and 2006 (Ng et al. 2009), with much of this decline due to falling levels of occupational and domestic physical activity (Ng et al. 2014). At the same time, leisure-time physical activity levels have generally remained stable for the majority of the population (Ng et al. 2014).

New technologies are changing, shifting, and refining our perspectives on physically active and sedentary behaviours and creating new research agendas. The rapidly growing use of consumable wearable technologies and smart phones/watches (which have inbuilt accelerometers) is also providing unique opportunities to monitor, and potentially intervene, on physical activity and sedentary behaviour (Althoff et al. 2017; Phillips et al. 2018).

Until recently, surveillance studies examining the population prevalence of physically active and sedentary time (such as those described earlier) have typically relied on time-use and self-reported moderate-vigorous physical activity during leisure time, or people's estimates of overall daily sitting or television/screen viewing time. However, activity monitoring using accelerometers (which can record time, duration, frequency, and intensity of movements) and inclinometer-accelerometers (which can provide more accurate data on sitting, standing, and stepping) are starting to provide more accurate and precise measurement of activity levels across the day. It is important to note that both self-report and sensor-assessed methods have their strengths and limitations. Self-report is prone to recall and response bias, social desirability, or under- or over-reporting, while sensor-assessed measurements can be expensive in larger studies and are typically unable to differentiate between the different contexts of physically active and sedentary behaviours (Sallis and Saelens 2000; Prince et al. 2008; Healy et al. 2011).

A challenge for monitoring global physical activity levels is the variability between countries in the availability of current and representative data. Measures used to access physical activity can differ across countries, which creates challenges in comparisons (Varela et al. 2017). Regular, national surveillance of physical activity levels is generally concentrated in highly developed countries, while a number of low-and middle-income countries in Africa, parts of Latin America, and central Asia have limited or no data on their population's physical activity levels (Hallal et al. 2012). The Global Observatory for Physical Activity (GoPA!) recently developed a series of Country Cards to amalgamate information on country-specific indicators for physical activity surveillance, policy, and research data (Varela et al. 2017). The cards are intended to be used as an advocacy tool to promote greater awareness of, and investment in public health policy, research, and programmes relating to physical activity, which may be particularly valuable for low-and middle-income countries (Ramirez Varela et al. 2018).

Understanding and influencing physical activity and sedentary behaviour: an ecological perspective

Physical activity is broader than activities that constitute structured exercise or sport. It can also, and predominantly does, take place in a variety of different settings—including during leisure, transportation, and in the workplace or school environment. Similarly, when we think about sedentary behaviour, sitting occurs at desks in the workplace, watching television in the home, or driving a car for transport. Understanding the settings in which physical activity and sedentary behaviour take place, and the factors that influence these behaviours, is particularly important for identifying opportunities for public health interventions that do not exacerbate existing social disadvantage. Box 8.5.3 outlines three major settings in which physical activity and sedentary behaviour typically take place.

Box 8.5.3 Physical activity and sedentary behaviour settings

Leisure: Physical activity and sedentary behaviour performed during leisure is generally performed with a degree of volitional control relative to other settings such as the workplace or school environment. For many adults, physical activity comprises a small proportion of their total leisure time, if any. Instead, the majority of leisure time is spent in sedentary pursuits, such as watching television, using a computer, or socializing with friends.

Work: Physical activity performed at work is often termed 'occupational physical activity'. Jobs which require heavy lifting and other manual tasks have higher levels of occupational physical activity. With increasing automation within many industries and a large number of the workforce 'desk-bound', occupational physical activity has been decreasing over recent decades. Many workers (such as those in desk-based jobs, parts of manufacturing, transport) spend much of the day sitting. The workplace has therefore become a key target setting for reducing sedentary behaviour.

Transportation: Physical activity performed during transportation is often termed 'active transport'. Examples of this include walking or cycling to get to and from destinations, including public transport stops. The rates of active transport vary substantially across the world. For example, over a third of the population walks or cycles to work in China and the Netherlands, while fewer than 5% do so in Australia or the United States (Hallal et al. 2012). Cycling in particular, is very common in China, the Netherlands, and Denmark (Hallal et al. 2012), while the vast majority of people in Australia and the United States use cars to get to and from work. In addition to less time spent in physical activity, high car dependency means more time spent in prolonged bouts of sitting.

Conceptual models and theories can be helpful for public health practitioners who are interested in understanding why a behaviour does, or does not occur, and therefore how to best intervene for positive health outcomes. Ecological models are helpful frameworks that have been applied to assist our understanding of a variety of health behaviours (Owen et al. 2011). A strength of ecological models is that they can incorporate multiple theories within an overarching framework, and thus allow for a broader

approach to understanding potential determinants of major health risks and multilevel approaches for change (Sallis and Owen 2015).

Rather than focusing primarily on changing behaviour at the individual level—which poses limitations beyond the individual's control, ecological approaches also consider extrinsic influences on behaviour (see Fig. 8.5.2). The ultimate goal being to create environments and policies that make it safe, convenient, attractive, and economical to make health-promoting choices, and then motivate and educate people to take up those healthy options.

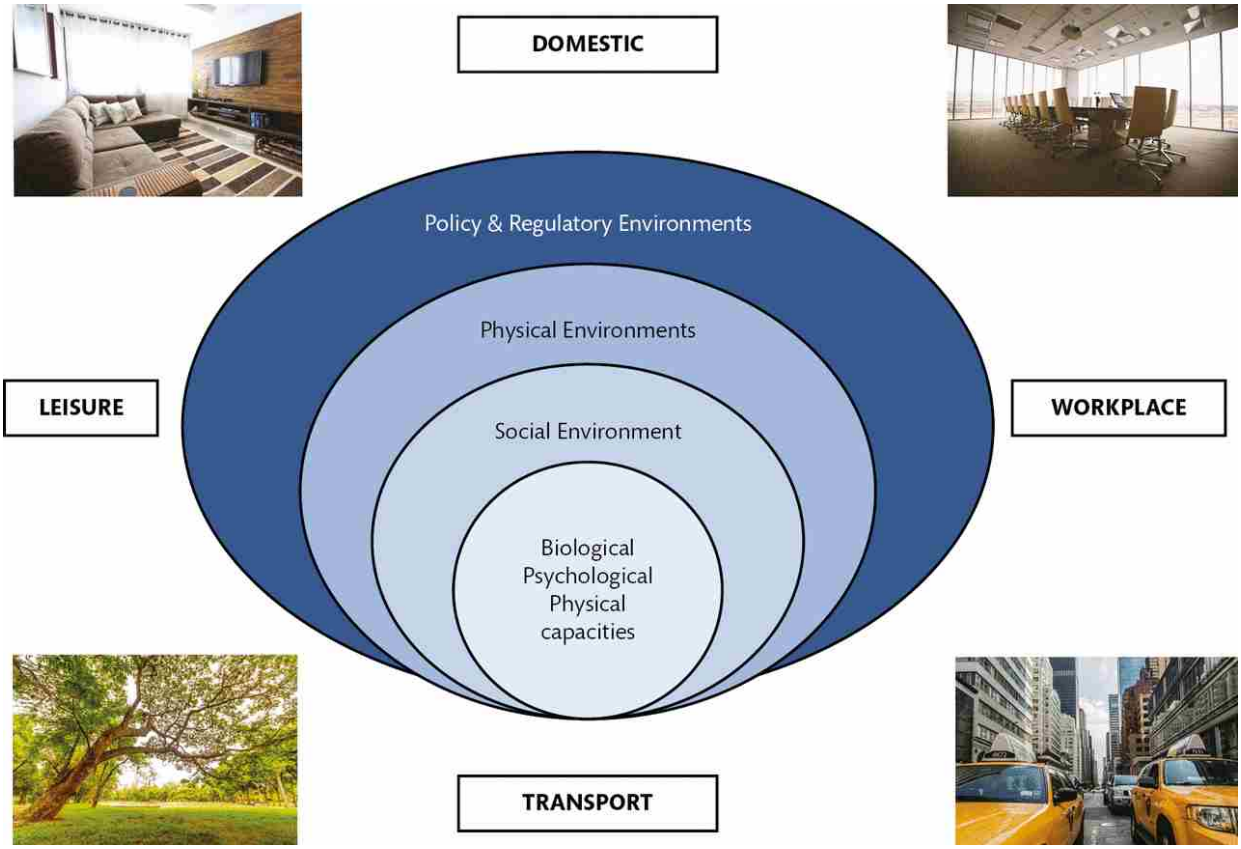

Fig. 8.5.2 A summary version of ecological models of physical activity and sedentary behaviour. Reprinted from Owen N et al (2011) 'Adults' Sedentary Behavior Determinants and Interventions' *Am. J. Preventive Medicine* 41(2):189–96, with permission from Elsevier.

Ecological models have five key principles as outlined to follow (Sallis and Owen 2015), which have relevance to approaches for influencing both physical activity and sedentary behaviour:

There are multiple levels of influence on health behaviours
Environmental contexts are significant determinants of health behaviours
Influences on behaviours interact across levels
Ecological models should be behaviour specific
Multilevel interventions should be most effective in changing behaviours

Considering these principles in the context of physical activity and sedentary behaviour, the influences on these behaviours are complex and multifaceted. These might include individual factors (such as preferences, abilities or motivation), social factors (e.g. extent of social support for activity, social norms), environmental factors (e.g. availability of equipment or proximity to pleasant surroundings for activity), and policy factors (e.g. workplace policies around active transport) (Owen et al. 2011). As these influences are hypothesized to interact across levels, interventions or strategies that focus only on one level of influence (such as individual, behavioural factors) are likely to be limited in their success at changing behaviour (Hadgraft et al. 2018).

A public health approach to addressing physical inactivity and sedentary behaviour recognizes that strategies premised on the idea of 'individual choice' will only go so far, and it is important to recognize and address the broader structural barriers many in the population face to being physically active. This includes the broader social and environmental conditions in which we live and work (Owen et al. 2014). The WHO emphasizes the importance of a systems-based approach for addressing physical inactivity; one that focuses on addressing both upstream policy approaches and downstream individual-focused strategies (WHO 2018).

Developing public health strategies to increase physical activity and reduce sedentary time

Following the release of the Toronto Charter for Physical Activity, an evidence review identified seven 'best investments' for physical activity that are considered to be applicable across population groups (see Box 8.5.4) (GAPA-ISPAH 2012). Importantly, these approaches target the multiple levels of influence of physical activity, incorporating upstream social and environmental approaches, with downstream individually focused approaches (WHO 2018).

Box 8.5.4 Seven best investments for physical activity

1. **Supportive school environments:** Prioritizing and resourcing physical activity (structured and unstructured) across the entire school day, through approaches that engage the entire school community.
2. **Transport policies and systems:** Promoting active transport by prioritizing walking, cycling, and public transport.
3. **Urban design infrastructure and regulations that support physical activity:** the built environment should support transport and recreational walking, cycling, and recreation, across different age groups.
4. **Physical activity integrated into primary healthcare systems:** physical activity should be promoted within primary healthcare as an important modifiable risk factor for non-communicable diseases.
5. **Education and awareness raising:** multiple approaches, such as traditional media, social media, and public education campaigns should be used to promote physical activity awareness and knowledge and shift societal norms.
6. **Whole-of-community approaches to physical activity:** Physical activity should be promoted across the life course, and programmes should be integrated across the multiple settings in which people spend their time (e.g. workplaces, schools, community settings).
7. **Making sport programmes accessible for all:** promoting physical activity through sport by making sure it is enjoyable and accessible for people of different ages, gender identities, abilities, and across the socioeconomic spectrum.

Many of the best investments for physical activity may also have a positive effect on reducing sedentary behaviour; for example, mass media campaigns, infrastructure, and policies that promote walking and cycling, rather than car use (Scheepers et al. 2014). While there is a smaller body of knowledge about what works for reducing sedentary behaviour relative to physical activity, evidence suggests that environmental modifications in the workplace environment, such as the implementation of sit-stand workstations, can lead to significant reductions in sitting time (Neuhaus et al. 2014; Chu et al. 2016). In line with the ecological model of health behaviours, these types of interventions appear to be more effective when included as part of a multicomponent approach that targets multiple levels of influence (Chu et al. 2016).

In accordance with a key principle of ecological models, it is important that public health strategies for increasing physical activity and reducing sedentary behaviour are specific to the context in which these behaviours occur. As outlined earlier, physical activity and sedentary behaviour can

occur in multiple settings and contexts. The main factors that influence time spent in physical activity and sedentary behaviour in each of these settings are not necessarily the same, and understanding these differences is important for intervention development (Owen et al. 2011). Designing effective interventions requires identifying the settings-specific determinants or influences on these behaviours, to enable the development of appropriately targeted strategies. Importantly, consideration should also be given to the equity of physical activity initiatives, including providing no- or low-cost strategies where possible (Boxes 8.5.4 and 8.5.5).

Box 8.5.5 Examples of settings-based approaches for increasing physical activity and/or reducing sedentary behaviour

Workplace

- Introduction of sit-stand workstations to address the significant influence of desk-based work on sitting time (Neuhaus et al. 2014)
- Modifying the internal physical environment to promote stair use (e.g. through attractive design, point of decision prompts) and providing end-of-trip facilities to support active transport (Oldenburg et al. 2002)

School

- Walking School Bus programmes to encourage children to walk to school rather than being driven (Mendoza et al. 2011).
- Incorporating physical activity into academic classes and promoting physical activity breaks during lessons (Watson et al. 2017)

Transport

- Building safe and separated bicycle lanes to encourage active transport (Pucher and Buehler 2008)
- Reducing the availability of free car parking to promote use of active and public transport (Scheepers et al. 2014).

Community

- Organized activities in public spaces (e.g. tai chi, dance class, yoga) (Heath et al. 2012)
- Community walking groups (Kassavou et al. 2013)

It is worth noting that much of the evidence on ‘what works’ for increasing physical activity and reducing sedentary behaviour has arisen from controlled research studies in high-income countries, with relatively short-term follow up durations (Foster et al. 2005). Evidence for the effectiveness of community-wide interventions is somewhat inconsistent, potentially due to methodological issues of studies and the challenges inherent with population-level approaches (Baker et al. 2015). To increase our knowledge about the types of population-level physical activity interventions that are both effective and cost-effective, funding and resources should be prioritized towards conducting longer-term and more rigorous evaluations of these types of approaches (Laine et al. 2014; Reis et al. 2016). In particular, it is important to access the efficacy of approaches in a diversity of populations, including those from low-middle-income countries, less privileged backgrounds, those with disabilities, and those from culturally and linguistically diverse backgrounds.

Cities and transport systems, physical activity, and sedentary time

One significant set of challenges (and potential opportunities) for public health has been the rapid urbanization of developing countries around the world. As greater proportions of the population transition from rural to urban living, there can be benefits to public health through better access to healthcare and reduced incidence of infection (Leon 2008). However, these benefits are counteracted by a rise in non-communicable diseases, such as diabetes and cardiovascular disease (Yusuf et al. 2001), brought about by risk factors such as poor nutrition, insufficient physical activity, and high levels of sedentary time (Popkin 2004).

While traditional approaches to urban transport have considered how we can design safer roads for cars, there is now increasing interest in the ‘walkability’ of urban environments, or how features of the built environment may promote or discourage physical activity (Giles-Corti et al. 2016). Evidence from large cross-country studies has shown that particular urban design features can significantly influence the amount of time people spend in physical activity (Sallis et al. 2016). Higher connectedness of streets, higher density (to support mixed development and public transport), and the availability of local destinations are associated with higher levels of

walking for transport (Giles-Corti et al. 2016). Cycling is also more common in areas where there is supportive infrastructure—such as networks of separated bicycles lanes and bicycle parking (Pucher and Buehler 2008; Hallal et al. 2012). An advantage of walking and cycling is that they are low to no cost, meaning that they are broadly accessible to a large proportion of the population (i.e. those who have the physical capacity to walk or cycle). This makes walking in particular a feasible and accessible strategy for people as they age.

Increasing the number of trips that are conducted by active transport and reducing the amount of time that people spend in cars may also have broad-ranging benefits for public health beyond impacts on physical activity levels. Car time, for example, has been associated with a number of risk factors for chronic disease, including higher waist circumference, BMI, fasting plasma glucose and a clustered cardiometabolic risk score (Sugiyama et al. 2016). Reducing car emissions will also have broader environmental and health benefits (Woodcock et al. 2009).

The International Physical Activity and the Environment Network

In addressing key elements of the environmental and policy agenda advocated earlier, the International Physical Activity and the Environment Network (IPEN) project was established in 2004. IPEN has been working as an international team from 12 countries (Australia, Belgium, Brazil, Columbia, Czech Republic, Denmark, China, Mexico, New Zealand, Spain, the United Kingdom, and the United States), carrying out studies to identify neighbourhood environmental factors associated with physical activity and sedentary behaviour.

Several findings with important public health implications have emerged. The IPEN project has measured physical activity using accelerometer devices, has examined variations by country in activity levels and participants' perceptions of a range of built-and natural-environment attributes of their neighbourhoods, and has employed geographic information system databases to provide objective indices of environmental factors (see Fig. 8.5.3 for country-specific examples).

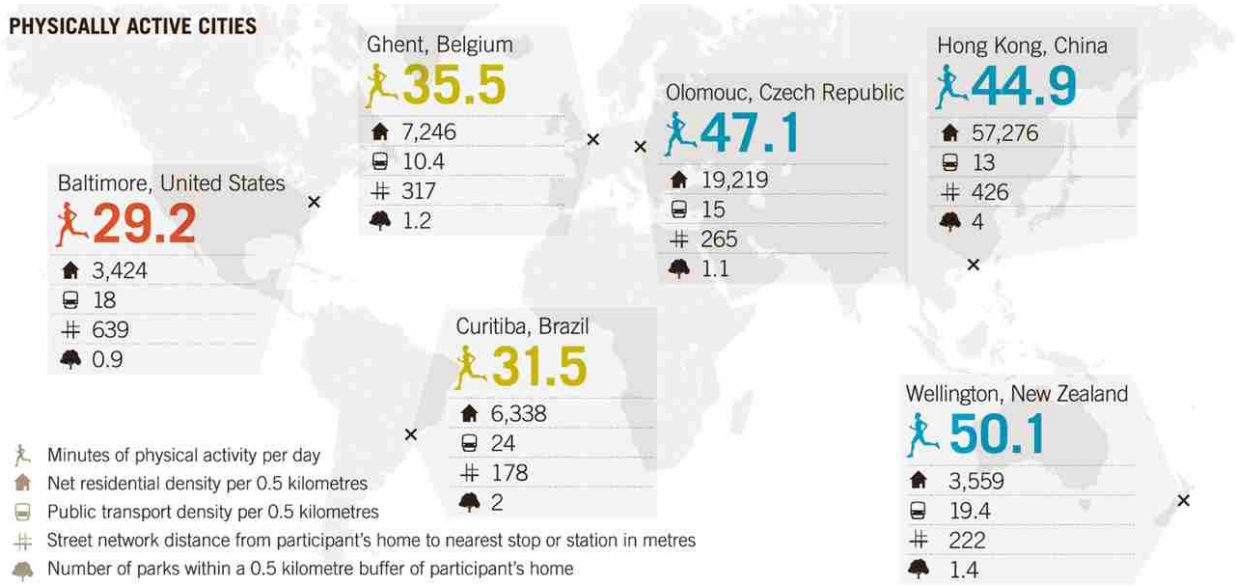

Fig. 8.5.3 Examples of country-specific activity levels and related environmental attributes, from the IPEN project.
Source: J. F. Sallis et al. The Lancet 387, 2207–2217 (2016).

In identifying associations of neighbourhood environmental attributes with physical activity and health, using the 'walkability' construct (a composite measure employing indices of net residential density, intersection density, land use mix, and net retail area ratio) has been particularly informative.

Through the IPEN project, interesting findings have emerged on the role that the built environment may play in promoting or discouraging physical activity. Based on data from 14 cities in 10 countries, several neighbourhood environment attributes were related consistently to accelerometer-assessed moderate to vigorous physical activity. These included:

residential density
number of public transport stops
number of street intersections
and, number of parks within walking distance

The relationships were linear; for example, the higher the level of residential density was related to a correspondingly higher level of physical activity. Those living in the most 'activity-friendly' neighbourhoods did 68–89 minutes more of physical activity per week than those in the least activity-friendly neighbourhoods (Sallis et al. 2016).

The IPEN project has identified considerable similarity of findings across the cities investigated, adding strong evidence to support previous calls for policy changes in urban planning, public transport, and development of parks and recreational facilities as ways to increase physical activity. It is of considerable interest that 'activity-friendly' neighbourhood characteristics were found to be related to physical activity in a linear fashion—suggesting that every improvement in the built environment of a city can be expected to help to increase physical activity, whether or not residents are starting at a low or high level. These findings, however, are from a set of developed countries. Comparable findings have emerged from studies in Japan (Liao et al. 2016). Whether such environmental attributes are similarly important in low- and middle-income countries remains to be determined.

Creating environments in cities that promote, rather than discourage, activity will require the involvement of (among others) urban planners, engineers, and policy makers at different levels of government, alongside public health practitioners. Shared decision making and building trust with stakeholders from the variety of sectors involved is important for effective intersectoral action to create healthy cities (Barr et al. 2008).

Conclusions

While efforts to understand and influence physical inactivity have been a public health priority for several decades, progress in improving the physical activity levels of populations has been modest (Heath et al. 2012). Understanding how to address low levels of physical activity in populations that are increasingly urbanized, automobile dependent, and captured by screens in their domestic and workplace environments is a complex issue, like many public health challenges.

Public health initiatives focused on creating healthy and enabling environments, such as through targeting urban planning and the built environment attributes of cities, offer great potential to improve health outcomes. Such approaches would not only have positive benefits on and through physical activity, but also through influencing other adverse exposures such as air pollution, noise, stress, and limited access to good-quality food (Giles-Corti et al. 2016).

The causes of low levels of physical activity and high levels of sedentary behaviour are multifactorial, and different approaches are likely to be

necessary depending on the setting and the population group of interest. To achieve large-scale change, interventions and policies will need to be developed using intersectoral and systems-based approaches, as well as perspectives that incorporate broad-ranging expertise and recognize the influence of traditional non-health sectors on health risk behaviours and outcomes.

Diabetes mellitus

Farah Naz Khan, Nida Izhar Shaikh, K.M. Venkat Narayan, and Mohammed K. Ali

Introduction

Diabetes: definition, classification, and diagnosis

Definition and classification

Diabetes mellitus is a complex chronic disease characterized by elevated blood sugars. The term *diabetes* has Greek origins and was meant to describe the passing of urine, while *mellitus* stems from the Latin word for sweet. Elevated blood sugars or hyperglycaemia seen in diabetes can be attributed to either impaired insulin production, impaired insulin action, or both (American Diabetes Association 2018). Produced by the beta cells in the pancreatic islets of Langerhans, insulin is the main hormone responsible for regulating glucose. In response to elevated blood sugars after food intake, the pancreatic beta cells secrete insulin, thereby facilitating the utilization of glucose and keeping blood glucose within an acceptable normal range. Prolonged hyperglycaemia over many years can cause damage to both large (macrovascular) and small (microvascular) blood vessels. The macrovascular complications from diabetes include coronary artery disease, cerebrovascular disease, and peripheral arterial disease, and microvascular complications encompass retinopathy (which can lead to vision loss), neuropathy (which can contribute to foot ulcers), and nephropathy (which can culminate in end-stage renal disease). Epidemiological studies examining the sugar levels at which the risk of macrovascular and microvascular complications increase have influenced the thresholds that we use to define and classify hyperglycaemia and diabetes.

The American Diabetes Association (ADA) and the World Health Organization (WHO) provide widely recognized recommendations on the

classification and diagnosis of diabetes (WHO 2006); however, it is important to note that the distinctions between the types are somewhat arbitrary and factors separating them exist on a spectrum as shown in Figure 8.6.1. Notably, those with type 1 diabetes will require insulin for survival, whereas other classifications may potentially be managed with non-insulin therapies. The main categories of diabetes classification that will be discussed are type 1 diabetes, type 2 diabetes, and gestational diabetes.

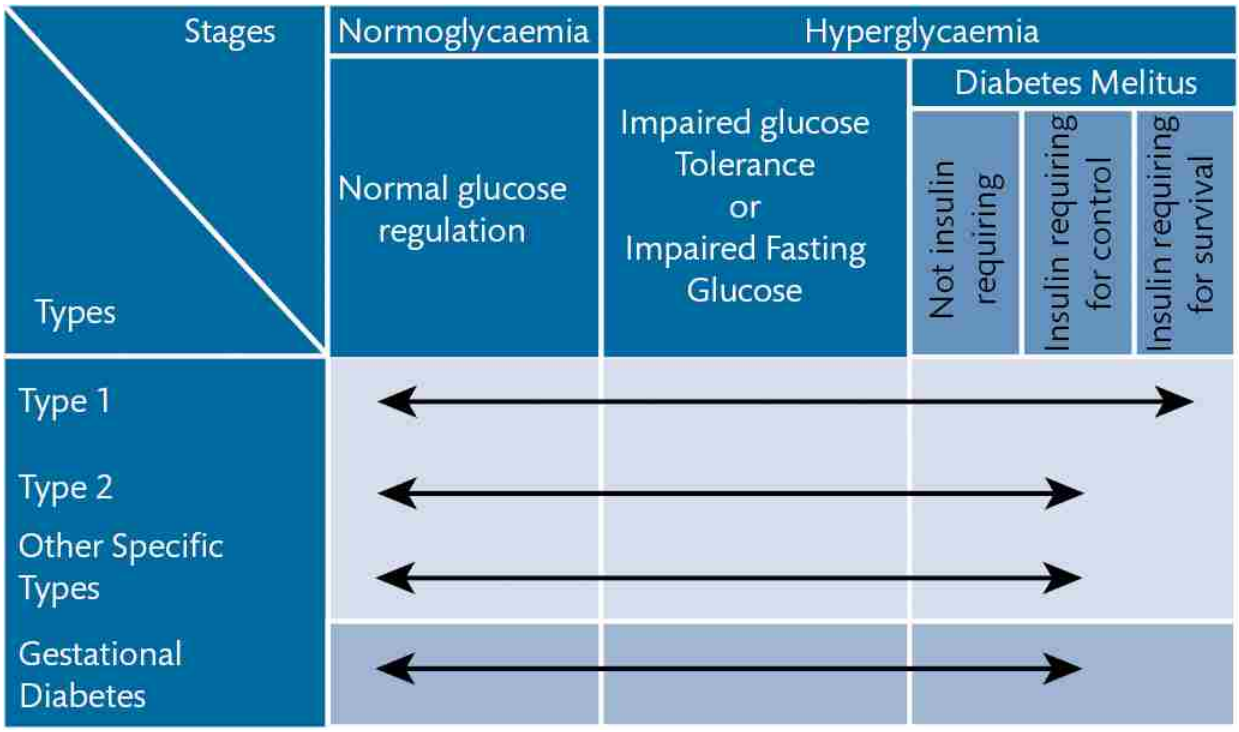

Fig. 8.6.1 Definition and diagnosis of diabetes mellitus and intermediate hyperglycaemia.
Reprinted from World Health Organization and International Diabetes Federation (2006). 'Definition and diagnosis of diabetes mellitus and intermediate hyperglycemia. A report of a WHO/IDF Consultation.' With permission from the WHO. Available from http://www.who.int/diabetes/publications/diagnosis_diabetes2006/en/.

Type 1 diabetes is caused by the destruction of insulin-producing pancreatic beta cells. Most commonly, this is due to autoantibodies against the beta cells, but can been seen in post-pancreatectomy patients and in patients with chronic pancreatic inflammation or injury. Type 1 diabetes accounts for only a minority of diabetes across the world.

A milieu of impaired metabolic functions contribute to the development of type 2 diabetes including: impaired pancreatic insulin secretion, increased hepatic gluconeogenesis, decreased incretin effects, decreased skeletal muscle glucose uptake, increased lipolysis, neurotransmitter dysfunction, and increased renal glucose reabsorption (Defronzo 2009).

Gestational diabetes is similar to type 2 diabetes in that it occurs as a result of insulin resistance and impaired insulin secretion as opposed to the beta cell destruction seen in type 1 diabetes. Diagnosed either in the second or third trimester of pregnancy, gestational diabetes usually resolves after delivery. However, women with gestational diabetes have over 7 times higher risk of developing type 2 diabetes compared to women with normoglycemic pregnancies (Bellamy et al. 2009).

There are also other (relatively) rare and specific forms of diabetes that include: (i) exocrine pancreatic insufficiency related diabetes such a cystic fibrosis-related diabetes; (ii) monogenic diabetes syndromes such as neonatal diabetes and maturity-onset diabetes of the young; and (iii) medication-related diabetes such as steroid-induced diabetes.

Diagnosis

Diagnosis of diabetes relies on blood glucose levels, which can be done to reflect fasting serum glucose levels, 2-hour post-load glucose levels, or a combination of the two. These can be done as part of an oral glucose tolerance test (OGTT). OGTTs detect impaired glucose metabolism as the test measures blood glucose before and then 2 hours after the ingestion of a glucose load. The OGTT is often considered too cumbersome and more costly than using a fasting glucose alone, which is why the ADA prefers the use of fasting plasma glucose or glycated haemoglobin (HbA1c) for diabetes diagnoses. Glycated haemoglobin is a non-fasted test that reflects the average blood glucose over the previous 8–12 weeks (Nathan et al. 2007). This being said, the OGTT remains the best test to detect those with impaired glucose tolerance who have normal fasting blood sugars (Balkau 2000), so it is still favoured as the diagnostic method of choice by the WHO. The latest ADA and WHO criteria for diagnosis of diabetes are summarized in Table 8.6.1 (WHO 2006; American Diabetes Association 2018), which includes the WHO 2011 special consultative report that also endorsed the HbA1c as a diagnostic test (WHO 2011).

Table 8.6.1 ADA and WHO diabetes and non-diabetes hyperglycaemia diagnostic criteria

	ADA	WHO
Diabetes		
Fasting glucose	≥7.0 mmol/L	
2-hour glucose	≥11.1 mmol/L	
HbA1c	> 6.5%	
Impaired fasting glucose		
Fasting glucose	5.6 to 6.9 mmol/L	6.1 to 6.9 mmol/L
2-hour glucose	n/a	
Impaired glucose tolerance		
Fasting glucose	<7.0 mmol/L AND	
2-hour glucose	≥7.8 and <11.0 mmol/L	
Prediabetes		
HbA1c	5.7% to 6.4%	n/a

The diagnostic criteria noted in Table 8.6.1 could all be used individually to diagnose diabetes, impaired fasting glucose, or impaired glucose tolerance. The largest discrepancy is in the criteria for impaired fasting glucose (IFG), where the ADA and WHO differ slightly. The ADA also uses HbA1c values of 5.7% to 6.4% to diagnose prediabetes, which encompasses those who are at increased risk of developing diabetes. While the HbA1c test may seem to be the simplest tool given its ability to give average blood glucose over time with a simple non-fasting blood test, it was initially not recommended by the WHO as a diagnostic test (WHO 2006). The WHO's main concerns involved cost and availability, international laboratory consistency, and HbA1c's variability with health conditions that affect red blood cell turnover, as is the case for sickle cell anaemia. These concerns remain valid, and should be kept in mind when using HbA1c as diagnostic tool across populations.

Diabetes: worldwide prevalence and trends

The burden of diabetes across the world has been steadily increasing in both men and women since 1980 (NCD Risk Collaborators 2016). Over time, diabetes prevalence has increased in every country studied. This increase in diabetes prevalence was most strongly associated with ageing and growth of populations, and to some extent, to changes in lifestyles (NCD Risk Collaborators 2016).

The International Diabetes Federation (IDF) has tracked diabetes prevalence for nearly two decades. In the most recent Diabetes Atlas, the IDF estimates that there are 463 million adults age 20–79 years who have diabetes. Unfortunately, almost half of those with diabetes are thought to be unaware of their diagnosis. Figure 8.6.2 illustrates the millions of adults across the world living with diabetes. This population is expected to grow to 700 million by the year 2045. Additionally, hyperglycaemia in pregnancy is estimated to affect 16.2% or 21.3 million live births across the world (Cho et al. 2018).

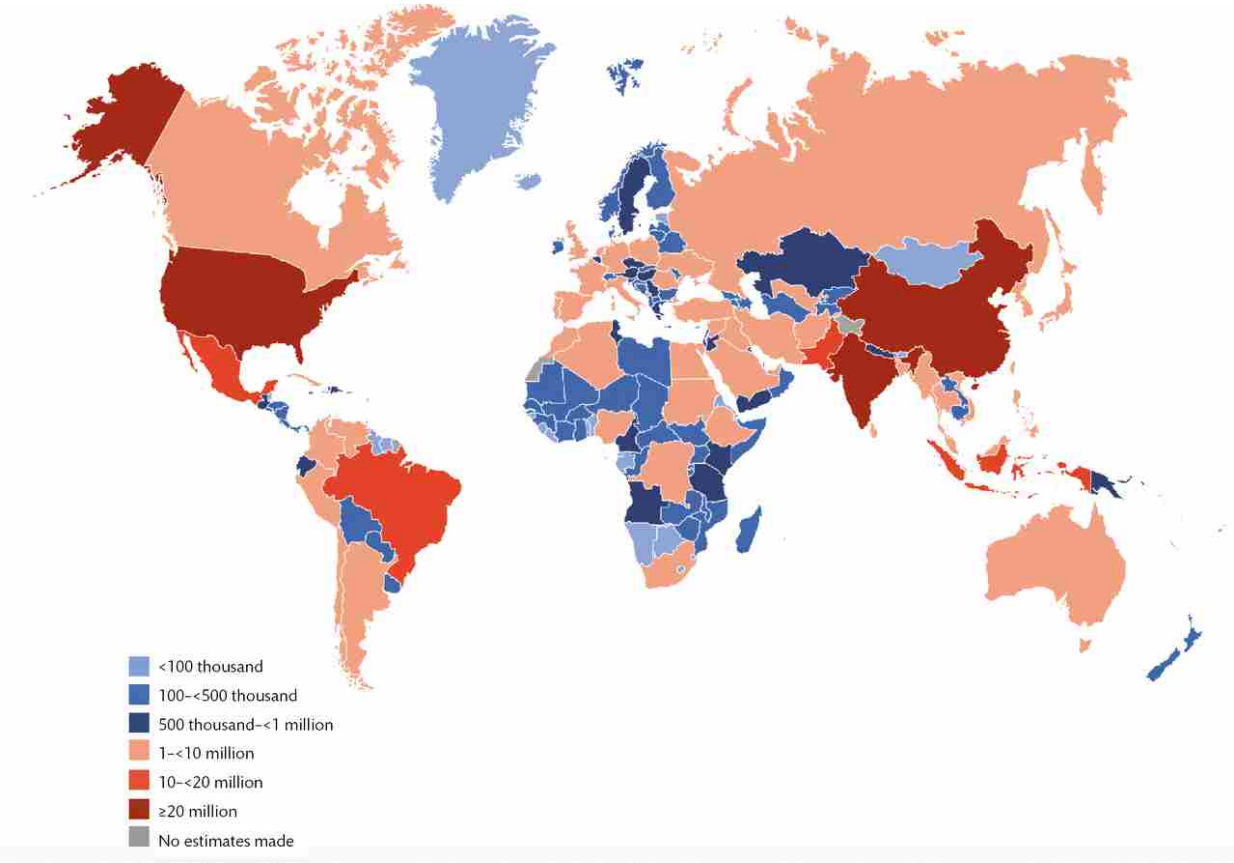

Fig. 8.6.2 Estimated total number of adults living with diabetes, 2017.
Reproduced from International Diabetes Federation, Diabetes Atlas, Ninth Edition, Map 3.1, International Diabetes Federation, Brussels, Copyright © 2019.

Of note, women have slightly lower prevalence than men and the burden of diabetes is most prevalent in the 65–79 year age group (Fig. 8.6.3). The prevalence of diabetes is higher in urban compared to rural environments (10.2% vs. 6.9%). North America, the Middle East and North Africa, and Southeast Asia have the highest diabetes prevalence currently. These trends and findings are also corroborated by other large comprehensive analyses as shown in Figure 8.6.4 (NCD Risk Collaborators 2016).

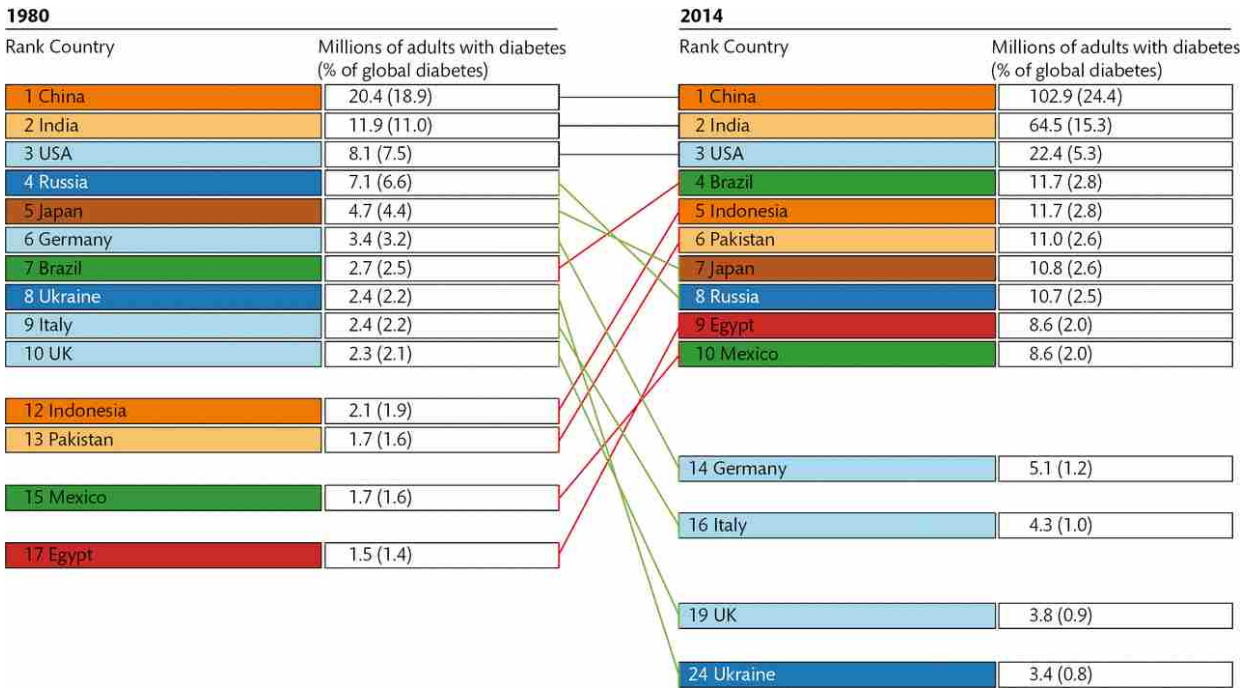

Fig. 8.6.4 Ten countries with the largest number of adults with diabetes in 1980 and 2014.
Reprinted from Zhou B. et al (NCD Risk Factor Collaboration, NCD-RisC) (2016) Worldwide trends in diabetes since 1980: a pooled analysis of 751 population-based studies with 4·4 million participants. *The Lancet*. 387:10027, 9–15 Pages 1513–30 under a CC BY 4.0 license.

Over 75% of the IDF's estimated 463 million people with diabetes live in low- and- middle-income countries (LMICs). The IDF and NCD-RiSC Collaboration show that the largest and fastest increases in diabetes prevalence in the coming years will occur in LMICs (NCD Risk Collaborators 2016; Cho et al. 2018).

Contributions of diabetes to global burdens of disease

Disease burdens are most commonly evaluated in terms of health, economic, and social impacts. In terms of health burdens, diabetes-related complications can be acute where extreme fluctuations in blood glucose require urgent medical care to sustain life, or can be chronic when diabetes has been poorly controlled for long periods of time. Chronic complications are most commonly characterized by disruptions in blood flow (due to damage to the vasculature) to the heart, brain, eyes, kidneys, or limbs, but can also include mental health and infectious disease outcomes.

The risk of cardiovascular disease in people with diabetes is two- to fourfold higher than in people without diabetes (Stamler et al. 1993; Folsom et al. 1997), and this accounts for much of the increased mortality associated with diabetes (Roglic et al. 2005). Diabetes is the leading cause of renal failure in high-income countries (HICs), responsible for 40–50% of all new patients requiring dialysis in United States and Canada, and 15–33% in Europe and Australia (Atkins 2005). The nerve damage associated with diabetes can affect both peripheral and autonomic nerves. Peripheral nerve damage and disruption in peripheral vascular blood flow lead to diabetic limb and foot disease, which can culminate in amputations if untreated (Edmonds et al. 1996). In HICs, diabetes is the single most important cause of non-traumatic lower limb amputation, accounting for 40–60% of all amputations (Unwin 2000), and people with diabetes have a 15-fold higher risk of amputation compared to people without diabetes (Edmonds et al. 1996). Individually and together, these conditions result in considerable morbidity, decreased quality of life, higher use and costs of healthcare, and increased mortality.

Notably, while most other causes of mortality are declining worldwide, diabetes-related mortality has remained flat and/or increased (Ali et al. 2015). Annually, diabetes contributes to approximately 5 million (8.4%) of all deaths, and LMICs appear to shoulder nearly four-fifths of these deaths (Cho et al. 2018).

In addition to premature mortality leading to lost productivity, diabetes is a costly condition requiring long-standing and progressively more healthcare visits and medical treatments. Currently, it is estimated that diabetes results in nearly US$1 trillion direct medical expenditures annually. Diabetes also results in higher and growing non-medical costs for people with diabetes and their caregivers worldwide. At an individual level, the costs of care increase dramatically with the presence of complications; being two- to threefold higher with the presence of either micro- or macrovascular complications, and five- to sixfold higher with the presence of both micro- and macrovascular complications than in people with diabetes without complications (Williams 2005). Diabetes, as with any other chronic illness, may limit employment and impact upon the income of people with it and the people caring for them. In 2007, the impact of diabetes on gross domestic product (GDP) was estimated for several countries; the United Kingdom lost

0.4% of GDP, the US 1.2%, and India 2.1% (Economist Intelligence Unit 2007).

Efforts to characterize the social impacts of diabetes have noted that this disease interferes with societal roles and functioning, increases the need for long-term care (at home or in facilities) to support people with physical deficits of diabetes like amputations or need for dialysis, and leads to mental health manifestations such as depression, cognitive dysfunction, impaired social integration, and poorer quality of relationships. These costs to society, along with their associated psychological harms, are extremely hard to quantify tangibly.

Challenges in different settings—LMICs vs. HICs

Compared to HICs, LMICs often have worse health outcomes in the face of limited access to routine care, medications (e.g. insulin), and infrastructural resources (e.g. refrigeration for insulin) that can be lifesaving (Sobngwi et al. 2012). With regard to diabetes-related complications, there have been large reductions in classic complications of type 2 diabetes, predominantly reductions in myocardial infarctions, stroke, amputations, and mortality in HICs (Gregg et al. 2016). However, trends in burdens of diabetes-related complications in LMICs have been unclear (Gregg et al. 2016). Diabetes and diabetes-related complications are seen more commonly among youth and adults ages 15–69 years in LMICs versus among adults ≥65 years in HICs.

While LMICs shoulder disproportionate burdens of diabetes, research into diabetes remains concentrated in a few HICs (Narayan 2016). The discordance in research outputs and research capacity between HICs and LMICs has implications for policies and decision-making. Research capacity in LMICs is insufficient and often fragmented. Locally led diabetes research in LMICs is critical to the proposal of culturally suitable and cost-effective interventions. Additionally, local research in LMICs will help better investigate obstacles that prevent recommended strategies from being implemented.

Phenotypic differences

People with either IFG (higher-than-normal fasting blood glucose levels) or impaired glucose tolerance (IGT, higher-than-normal post-prandial blood

glucose levels) or both are all considered to have prediabetes despite their potential phenotypic and physiologic differences. The IDF estimates that 318 million people (6.7% of the adult population) worldwide have some form of IGT, but the IDF estimations do not include individuals with isolated IFG (iIFG) or fully capture those with combined IFG-IGT (International Diabetes Federation 2013). Estimates regarding the distribution of the subtypes of prediabetes worldwide are not available because the blood tests required to diagnose prediabetes are relatively expensive and logistically inconvenient to administer (Ali et al. 2017). This lack of data has major implications for understanding the natural history of different types of diabetes and implementing appropriate interventions.

The aetiologies, clinical presentations, diagnoses, treatments, and prevention of these different phenotypes of diabetes and prediabetes differ (Ahlqvist et al. 2018). As an example, when comparing Pima Indians vs. Asian Indians (Narayan 2016), the Pimas represent an obese, highly insulin-resistant phenotype, unlike South Asians who exhibit a relatively thin insulin secretory deficit phenotype. Studies examining the South Asian phenotype suggest that generations of undernutrition may underlie a greater propensity to fat storage, insulin resistance, and early problems with insulin secretion (Enas et al. 2007; Unnikrishnan et al. 2014; Narayan 2016). This geno- or epigenetic vulnerability is then triggered by lifestyle choices—of note, South Asians exhibit a high prevalence of smoking and heavy alcohol use, high intake of refined carbohydrates (e.g. white rice), and decreased physical activity levels (Hu 2011). Despite the influence of lifestyle factors, studies examining the effectiveness of lifestyle modification among people with thin, metabolically unhealthy profiles have shown modest benefits at reducing diabetes incidence (Absetz et al. 2007; Weber et al. 2016). This may be because early β-cell dysfunction is a more dominant pathophysiology in these subgroups, and this phenomenon is quite common in populations of emerging economies (Chan et al. 2004; Maskarinec et al. 2009; Gujral et al. 2013; Mohan et al. 2013; Gujral et al. 2014; Staimez et al. 2013; Sattar and Gill 2015). South Asian populations appear to have a higher susceptibility for poor β-cell function compared to their counterparts in Europe (Ikehara et al. 2015), US (Kanaya et al. 2014), and Netherlands (Jainandunsing et al. 2015). However, most of the published data are from cross-sectional studies, and investments in longitudinal multiethnic studies are needed to establish causality and mechanism (Narayan 2016).

The impacts of diabetes also vary by ethnicity. For example, South Asians are five to nine times more likely than other racial/ethnic groups to exhibit dyslipidaemia (characterized by low HDL cholesterol and high triglycerides), even at a healthy BMI (Patel et al. 2016; Gujral et al. 2018). In the United States, people with diabetes of African, Asian (Chinese and Japanese), and Hispanic origin have substantially lower rates of myocardial infarction than those of European origin, and those of the latter two groups have lower rates of stroke. Similar findings were seen for people of African origin in the United Kingdom (Davis 2008). People with diabetes of South Asian origin are at similar or higher risk of cardiovascular disease than those of European origin (Gholap et al. 2011). These differences are not fully explained by differences in conventional risk factors.

Studies have reported marked differences by ethnic group in the risk of end-stage renal disease, with people of African and Asian origin in particular being at greater risk compared to those of European origin (Karter et al. 2002; Lanting et al. 2005). A high risk of diabetes-related renal disease has also been described in Asia (Chan et al. 2009). Differences exist in the risk of lower extremity amputation by ethnic group, for example: people of Asian origin in the United States and United Kingdom having a markedly lower risk than the European population (Lanting et al. 2005; Chan et al. 2009).

Unfortunately, the relative contributions of healthcare access, health behaviours, and genetic susceptibility to these ethnic group differences are not completely understood (Karter et al. 2002; Lanting et al. 2005).

Differences in access and care

In HICs, people typically access diabetes care through insurance-financed health care, whereas in LMICs, the majority self-pay to get access to care, thereby often impoverishing individuals and families. Varied access and low-resource settings affect care and outcomes for diabetes. In LMICs, resources are scarce in the face of rapidly increasing need. Low-resource settings face numerous challenges in delivering diabetes care and education such as limited access to care; cultural, social, and financial barriers; and lower literacy levels.

There are large gaps in care in both HICs and LMICs. With the growing availability of mobile phones and access to internet worldwide, not only do HICs, but also LMICs have the opportunity to benefit from SMS-based services that can address the problems of access to diabetes care. Even still,

data from Africa, Asia, Europe, Latin America, and the United States show that more than half of the people with diabetes are not meeting recommended targets to prevent complications (Gakidou et al. 2011; Sobngwi et al. 2012; Ali et al. 2013; Stone et al. 2013). Another study from eight countries in Europe showed that although 80–98% of people with diabetes had recorded values for glycated haemoglobin, blood pressure, and lipid values in the past year, few had achieved the recommended values (54%, 19%, and 55%, respectively) (Stone et al. 2013). In LMICs, there are almost no data representative of the entire population (Narayan et al. 2012). A study of six African countries reported that 47% of all respondents with diabetes had glycated haemoglobin levels recorded in the past year, 29% had glycated haemoglobin <6.5%, and only 13% and 65% were treated with lipid-lowering or antihypertensive medications, respectively (Sobngwi et al. 2012). In general, there is wide variation in the way different healthcare facilities, regions, and countries monitor, record, and report quality of care for diabetes across the world.

There are also large gaps in prevention of diabetes worldwide. In the United States, it is estimated the 90% of 84 million people with prediabetes who would be eligible for preventive services (Li et al. 2012) are not aware of their status and therefore not engaged in diabetes prevention programmes. Data from LMICs are lacking and we do not know the proportion of people who are at high risk for diabetes and are aware of their prediabetes status as glycated haemoglobin tests are costly and OGTTs are time consuming and disliked by patients.

Socioeconomic gradients

The prevalence and impacts of diabetes vary across geographical and socioeconomic contexts defined by rural versus urban, education levels, occupation, and income. Importantly, the patterns of these gradients appear to be at different stages in their evolutions in HIC and LMIC settings.

In LMICs, populations with higher education, those experiencing rapid industrialization, urbanization, international trade, migration from rural to urban centres, and lifestyle changes including diets high in calories, reduced physical activity, and tobacco use are experiencing faster and higher diabetes burdens (Robbins et al. 2005; Willi et al. 2007; Ramachandran et al. 2010; Anjana et al. 2011; Hu 2011; Lee et al. 2012; Xu et al. 2013; Dagenais et al. 2016).

In HICs, the relationship between socioeconomic status and diabetes appears to be reversed, with the poor at greatest risk and most burdened. For instance, strong associations have been observed between poverty, low education, and type 2 diabetes (Robbins et al. 2001; Krishnan et al. 2010; Sims et al. 2011). A recent meta-analysis of 23 case–control and cohort studies that examined SES–diabetes associations using 43 measures found an overall higher risk for type 2 diabetes among low SES groups based on education, occupation, and income (Agardh et al. 2011). The strength of the association, however, was less consistent in LMICs, where few studies have been conducted (Corsi and Subramanian 2012).

The changing face of diabetes globally

Diabetes remains a vast and significant global health problem. However, the epidemiology and burdens associated with diabetes are evolving as we learn more, implement prevention programmes, modify our approach to care delivery, and as other influential contextual factors change (e.g. in social, political, and economic circumstances). We will focus on a few key trends that are changing the face of diabetes globally.

First, the prevalence and incidence of type 2 diabetes in younger adults have been on the rise. Increasing incidence of type 2 diabetes in youth has been noticed over the past several decades, and this trend follows a growing burden of obesity in younger generations (Dabelea 2018), particularly so in minority and indigenous groups. The risk factors for young-onset type 2 diabetes share similarities with the predisposing risk factors found in those with older-onset—namely, adiposity and metabolic factors and family history, but additional factors, such as maternal obesity and diabetes during pregnancy or undernutrition *in utero* may play a strong role. The implication of earlier onset, prior to the age of 40, is that this increased exposure to diabetes leads to increased risk of long-term microvascular and macrovascular complications. Some evidence also suggests that younger onset type 2 diabetes may have a more aggressive presentation that results in earlier development of diabetes complications (Lascar et al. 2018); this has been shown in South Asian populations as well (Amutha et al. 2017). This calls for focused research in young type 2 patients to identify more effective means of preventing and treating early onset of diabetes.

Second, with greater access to effective diabetes care, lifespans of those with diabetes are also increasing (Gregg et al. 2016). Living longer with this chronic disease has three important implications:

The profile of diabetes complications is changing. Diabetes complications have traditionally been dominated by vascular diseases of the coronary, cerebrovascular, and peripheral vasculature; however, with successes in preventing and treating these macrovascular diseases and expanding life expectancy, there is now emergence of additional complications like cancers, infections, and mental health disorders in the ageing diabetes patient population. Furthermore, successes have not extended to declines in renal disease, and growth of this complication expands global financial and health impacts of diabetes.

There is a growth of multimorbidity in people with diabetes. Most adults with diabetes have at least one other chronic disease, and some estimates suggest, with longer life expectancy, as many as 40% of adults with diabetes would have accrued at least three other chronic diseases (Piette and Kerr 2006; Teljeur et al. 2013), which is often defined as ‘multimorbidity’. Multimorbidity complicates management of diabetes. For those caring for people with diabetes, additional comorbidities can often complicate the choice of treatments as some medications have deleterious effects on other organ systems. Furthermore, additional comorbidities come with added financial costs, as well as physical, mental, and emotional tolls that drastically affect self-care for many adults with diabetes. Together, more complex management, polypharmacy, and poorer self-care all increase risks of disability and mortality (Ekundayo et al. 2009), and increase the economic and social impacts of diabetes.

With continued differences in access to, and quality of delivery of effective prevention and management interventions, diabetes and its associated comorbidities have the potential to widen disparities in health even more, both across and within countries. This calls for policy action to identify ways to scale up effective prevention and treatments for diabetes, or suffer downstream population impacts of ‘unnatural’ selection.

Can the curve be bent? What can be done?

Once a disease of HICs, type 2 diabetes is now a global public health crisis that has spread to every country in the world. The dynamics of the diabetes epidemic are changing rapidly. We have identified three areas to address the diabetes epidemic.

Invest in research to understand and treat the different phenotypes of diabetes

Recent advances have substantially improved our understanding of the pathophysiology of diabetes, but the currently identified genetic susceptibility loci are insufficient to explain differences in diabetes risk across different ethnic groups or the rapid rise in diabetes prevalence over the past several decades (Hu 2011). An important area for future investigation of phenotypes relevant to type 2 diabetes prevention and treatment is the role of innate or early problems with insulin secretion. It is time to consider the pathophysiology of type 2 diabetes across the spectrum, from those dominantly affected by insulin resistance (type 2A) to those dominantly affected by insulin secretion (type 2B) and to tailor measures of prevention for different subpopulations based on the primary problem (Narayan 2016). For instance, the Asian Indian type 2 diabetes phenotype may involve greater innate insulin secretion problems, both in the fasting state and in response to glucose challenges. This has implications for both prevention and treatment.

Another area for future investigation is in diabetes translational research that is aimed at translating results from trials into everyday healthcare and community settings (Ali et al. 2012; Johnson et al. 2013). While studies including epidemiologic and randomized clinical trials have shown that type 2 diabetes is preventable through lifestyle (diet and physical activity) modifications, translating these findings into practice requires fundamental changes in public policies, social environments, and health systems. Diabetes translation issues are diverse and complicated, but identifying and understanding barriers and facilitators to diabetes translation in different settings is needed (Garfield et al. 2003). Another issue is the need for sustainable interventions—in particular how to sustain an intervention once the intensity and excitement of the study are over (Boothroyd et al. 1994; Haw et al. 2017).

More research is needed to understand how to better implement and sustain evidence-based diabetes care in the real world and that addresses important knowledge gaps, especially regarding implementation and scalability (Ali et al. 2017). There is a need to identify highest priority interventions, particularly to detect, prevent, and manage diabetes in LMICs (Ali et al. 2017). We need to identify research that explores the best life stage for diabetes prevention, better understand early life factors that predispose individuals and subpopulations to obesity and type 2 diabetes (Cunningham et al. 2014), and is directed at improved understanding of the potential role of early life determinants (e.g. the maternal environment) to help shape disease prevention programmes (Zimmet et al. 2014).

Lastly, it is also time for research that addresses the disconnect between where most of the research is done (HICs) and where most of the diabetes burden lies (LMICs). Overall, longitudinal data from LMICs are needed to understand the natural history of diabetes and whether different ethnic, genotypic, or phenotypic variants of prediabetes and diabetes progress differently.

Implement what we know

Prevention: To curb the escalating diabetes epidemic, investing in research to understand primary prevention and phenotypic treatment differences should be a global policy priority (Hu 2011). Efforts at primary prevention of diabetes can include targeted screening of people with risk factors to identify prediabetes and diabetes (Ali et al. 2017) and engaging in diabetes prevention strategies for those at risk for diabetes. Evidence suggests lifestyle modification and medications successfully reduced diabetes incidence and comorbidities of diabetes. And although scale up efforts are underway in several countries including Finland (Saaristo et al. 2010), United States (Albright and Gregg 2013), India (Ramachandran et al. 2006), and Australia (Dunbar et al. 2014), more needs to be done to recruit at-risk persons to join and complete these programmes.

Management: To improve the management of prediabetes and diabetes, and lower the risk of complications, we need to address patient-level, provider-level, and system-level barriers that block achievement of care goals (Ali et al. 2017). One proposed idea is to use metformin for people

with prediabetes to prevent diabetes incidence but this is not yet an approved indication for the drug (Moin et al. 2015).

Collaborative care to treat multimorbidities: Collaborative care models have shown some promise in reducing the physical and mental burdens associated with this multimorbidity. Guidelines often focus on individualized treatment of diabetes while efforts to scale tend to focus on standardized approaches. More research is needed to determine whether standardized versus individualized care can most help those with diabetes across the world (Coventry et al. 2015), but likely a careful approach that marries these two entities will be key in assisting people with diabetes to age healthily.

Invest in policies and models to narrow disparities

Studies to date have noted obesity-associated type 2 diabetes in youth, often in minority and indigenous groups (Cunningham et al. 2017b). The only way to curb this growing problem of younger onset type 2 diabetes may be to prevent obesity through lifestyle promotion and integrated cultural change. Research, programmes, and policies aimed at increasing physical activity and making healthier food options more affordable than calorie-dense fast foods are much needed. These cultural changes are of particular importance given the notion of social networks. The concept of the impact of social relationships on health and the so-called social spread of chronic disease was first described in early social network conceptual modelling work that was done in the 1970s (Berkman 2000). Over the years, the impact of social networks on health and mortality have been further analysed and examined, and the impact of social networks on the spread of obesity was described in 2007 (Christakis and Fowler 2007). A subsequent study published several years later found an association between incident type 2 diabetes and social contacts with diabetes or obesity. Further stratification of the results found that incident type 2 diabetes was associated with diabetes in siblings and obesity in spouses—and these associations led to higher individual incident diabetes risk in those individuals with high diabetes genetic risk scores (Raghavan et al. 2016; Cunningham et al. 2017a). More research into social networks and their contribution to the spread of type 2 diabetes and obesity may help elucidate solutions to help narrow disparities across patient populations. Ultimately, all programmes and policies need to recognize that

there are large disparities due to poverty, growing worldwide urbanization, and variable access to healthcare.

Conclusions

Diabetes is a burdensome, chronic, costly, and common disease. Diabetes burdens are felt in every corner of the globe and are evolving. The medical, scientific, and public health communities have made important strides towards improving the detection, prevention, and management of diabetes, but the agenda is still incomplete. There are still many unknowns in our understanding of what works for different phenotypes of diabetes, large gaps in implementation of what we know, and wide disparities in access and engagement with known interventions. Ultimately, given the multifactorial nature of diabetes, addressing and preventing its burdens requires concerted efforts at policy, programme, clinical, and individual levels (Hill et al. 2013).

Public mental health and suicide

Danuta Wasserman and Kristian Wahlbeck

Introduction to public mental health and suicide

As defined by the World Health Organization (WHO), mental health is not just the absence of illness, rather it is conceptualized as a state of well-being, in which the individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community (WHO 2013). Consequently, public mental health is not just about the occurrence and prevention of mental disorders in the population, but it also concerns the promotion of mental health and well-being. Thus, public mental health can be defined as actions aimed at developing the mental health of populations and producing healthy societies.

Public mental health research encompasses: research that describes collective experience, occurrence, distribution, and trajectories of positive mental health, mental health problems, and their determinants; research on mental health promotion and prevention of mental disorders; research on mental health system policies and governance; service delivery; and the organization of mental health services.

Mental health is more crucial today than it has ever been, due to the societal transition into the information society era. The population's mental capital (i.e. cognitive, emotional, and social-skill resources required for role functioning) is a prerequisite for the prosperity of individuals, companies, and societies. Mental health becomes more valuable and more vulnerable, due to the many stressors in information-driven economies. At the same time, in low-income countries, poverty, discrimination, and poor mental health form a vicious circle which becomes an obstacle to economic development (Patel and Thornicroft 2009; Patel et al. 2015).

The huge burden and costs of impaired mental health for individuals, families, society, and the economy call for actions to prevent mental ill-health and promote positive mental health and well-being. This necessitates public mental health actions, not only to treat, but also to prevent impaired mental health and promote positive mental well-being.

Magnitude and costs of mental health problems

The magnitude and costs of mental health and mental disorders is relatively neglected (Jané-Llopis et al. 2011; Wahlbeck 2015), in spite of data showing that mental health is a growing health challenge. The share of burden attributable to mental and behavioural disorders, which is already substantial, will probably increase steadily in the future. The rising burden from mental and behavioural disorders will impose new challenges on health systems worldwide.

The recent update of the Global Burden of Diseases study (Kassebaum et al. 2016) demonstrates the magnitude of the burden of mental health disorders. Disability-adjusted life-years (DALYs) include potential years of life lost, due to premature death and equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. DALY data indicate that mental disorders constitute a growing share of the global disease burden. From 2005 to 2015, mental and substance abuse disorders showed a worldwide increase in DALYs by 14.9%. A single major source of disability and premature death is major depressive disorder (MDD). From 1990 to 2015, depressive disorders increased in ranking from nineteenth to fifteenth place among leading causes of DALYs worldwide. In order of importance, other main causes of DALYs among mental disorders were anxiety disorders (1.0% of DALYs worldwide), drug use disorders (0.7%), schizophrenia (0.6%), and alcohol use disorders (0.5%) (Kassebaum et al. 2016). Self-harm, which in 2015 ranked number 21 among worldwide causes of DALYs, adds to the total impact of mental and behavioural disorders on population health.

The distribution of DALYs varies considerably between geographical regions. The relative contribution of mental and behavioural disorders is as a rule higher in developed economies. According to the Global Burden of Diseases study, depressive disorders accounted for the eighth leading cause

of DALYs in high-income regions, such as Australasia, Europe, and North America. In many Western economies, up to half of the disability pensions are granted due to mental disorders, especially depression. It is, thus, foreseeable that a continued increase in the standard of living globally will contribute to a continued epidemiological transition towards increasing public health impact of mental disorders. In many of the developed economies, depressive disorders rank third, fourth, or fifth among causes of DALYs (Murray et al. 2012; Kassebaum et al. 2016). In regions with high suicide mortality rates, such as Eastern Europe, Japan, and South Korea, self-harm ranks fifth or sixth among causes of DALYs.

The disabling burden of mental and behavioural disorders is almost the same for males and females, but the major contributing causes are different. The burden of depression is 50% higher for females than males. In contrast, the occurrence of alcohol and drug use disorders in males is nearly seven times higher than that for females, and accounts for almost one-third of the male burden of mental and behavioural disorders. In both low- and middle-income countries, and high-income countries, alcohol use disorders are among the ten leading causes of years lived with disability (YLD). This includes only the direct burden of alcohol dependence and problem use. The total attributable burden of disability, due to alcohol use, is much larger.

The Sustainable Development Goals (SDGs) have the primary target to reduce economic poverty and inequalities, improve environmental stability, as well as reassure education, good health, and well-being, for all genders (United Nations 2017). The SDGs have demonstrated the epidemiological shift from communicable diseases towards non-communicable psychosocial disorders, which constitute a global health challenge. Promotion of population mental health is important, as mental health has vast and global well-being consequences. The WHO Action Plan 2013–2020 on mental health, approved by Member States at the WHO World Health Assembly, is a milestone in acknowledging the importance of mental health and the well-being of entire populations (WHO 2013).

Available data confirm the immense disability burden of mental disorders, not only in terms of DALYs, but also in terms of other indicators, such as loss of work days, work life productivity, and poor quality of life (Wittchen et al. 2011). This is due to the critical combination of high prevalence and high level of associated impairments and disabilities of

mental disorders. Many mental disorders—anxiety, substance use, and somatoform disorders in particular—start early, which typically has adverse effects on further psychological and social development, thereby reducing school and academic achievement, social functioning, and social integration.

Compared to many somatic diseases, costs for mental disorders differ with disproportionately high indirect cost items (e.g. sick days, disability, early retirement, and deaths due to suicide) and relatively low direct costs of healthcare (i.e. low expenditures for diagnostic measures, treatment, and care). Mental disorders are dominant contributors to the global economic burden of diseases. The global cost of mental health conditions in 2010 was estimated at US$2.5 trillion, with the cost projected to surge to US$6 trillion by 2030. About two-thirds of the total cost comes from indirect costs, and the remainder from direct costs. Currently, high-income countries shoulder about 65% of the burden, which is not expected to change over the next 20 years (Bloom et al. 2011).

For instance, in Europe, depressive disorder is a major cause of lost productivity (Wahlbeck 2009). In 2004, economic costs of depression were estimated to be €250 per inhabitant, or €118 billion. In the United Sates, the economic cost of MDD was estimated to be $210.5 billion in 2010 (Greenberg et al. 2015). As mentioned earlier, direct costs account for only a minor part of the total economic burden (Sobocki et al. 2006). A majority of costs, between 65 and 85%, are indirect. Data from Europe indicate that costs for depression are increasing. Moreover, depression causes significant reductions of well-being and in health-related quality of life (Sobocki et al. 2007).

People with mental disorders, including substance use disorders, are at risk of suicide. Ninety% of suicides are estimated to be associated with mental disorders, mostly with mood disorders, like depression, which is associated with 60% of suicides (Mann et al. 2005), and also with alcohol use disorders. However, suicidal behaviour is usually an outcome of complex interactions of socioenvironmental, behavioural, and psychiatric factors. High-risk groups include those with severe somatic illness, the socially disadvantaged, those with recent loss, especially through suicide (Nordentoft 2007), and some migrant groups (Garssen et al. 2006; Westman et al. 2006; Gilliver et al. 2014). People with a history of suicide attempts are especially at higher risk of dying by suicide (Fleischmann et al. 2008).

According to WHO data, suicides (i.e. deaths caused from self-inflicted intentional injuries) amounted to 804,000 in 2012, which was 1.4% of the total world mortality (WHO 2014), ranging from 0.5% in the African region to 1.9% in the Southeast Asian region (Värnik 2012). However, the WHO estimate includes neither injury deaths of undetermined intent nor deaths from unknown causes, which are generally believed to conceal unrecognized suicides. Moreover, the data from all WHO Member States are not reported.

The estimated global suicide rate is 11.4 suicides per 100,000 inhabitants, including 15 suicides per 100,000 for males and 8 suicides per 100,000 for females (WHO 2014). For both males and females, the highest suicide rates are found in Europe, predominantly in Eastern Europe, that is, Lithuania, the Russian Federation, Belarus and, to a lesser extent, Finland, Hungary, and Latvia: a group of countries that share similar historical and sociocultural characteristics, as well as similar alcohol use patterns. Nevertheless, some similarly high rates are found in countries that are quite distinct in relation to these characteristics, such as Cuba, Japan, Sri Lanka, and South Korea. As a whole, the lowest rates are found in Islamic countries (Bertolote and Fleischmann 2009; WHO 2017b). Due to stigmatization and legal sanctions against suicide, underreporting of suicide rates in Muslim countries may partly contribute to the low suicide mortality rates reported (Khan and Syed 2011).

The male suicide rate is higher than the rate of females, with the exception of some Asian countries, where the sex differences for suicide are reversed, and young women are more at risk for suicide than men (WHO 2017a), mainly due to impulsive attempts using pesticides as the mode of attempt (Law and Liu 2008).

Suicide in later life is a global public health problem. Those aged 65 years and above are the demographic group that constitutes the highest suicide rate in most countries reporting suicide statistics to the WHO (Conejero et al. 2018). Non-fatal suicidal acts tend to be less common in this age group (Fässberg et al. 2012).

The epidemiology of adolescent suicide has shown striking changes over the last 100 years, with a steady decline in recent decades. One of the suggested factors explaining this trend is the growing use of antidepressants, especially selective serotonin reuptake inhibitors, in the adolescent population (Bursztein and Apter 2009). Even within countries,

there is significant variability in suicidal ideation and behaviours among adolescents of different ethnic backgrounds. In the United States, American Indian/Alaska Native youth tend to have the highest rates of fatal suicidal behaviour among all ethnic groups (Amitai and Apter 2012; Hern et al. 2014). There are similar findings for Inuit populations in Canada, and the Ethiopian population in Israel, with regards to fatal suicide. As well, the Amerindian population in French Guiana has very high suicide rates, in contrast with other French territories, with the younger age groups of both genders affected (Pacot et al. 2018). All of these youth show a similar pattern of failure to integrate traditional cultures with a modern Western culture (Amitai and Apter 2012). However, it is important to note the problems colonization has created for indigenous peoples. As those who have maintained control over their lands and culture have shown much lower rates of youth suicide, as found in British Columbia, Canada (Chandler and Lalonde 2008).

Suicide rates are higher in many disadvantaged populations groups, such as ethnic or sexual minorities. Family rejection or negative family reaction to an adolescent who is gay, lesbian, or bisexual is associated with an eightfold greater likelihood of attempting suicide compared to adolescents who experienced minimal or no family rejection (Ryan et al. 2009; Cotter et al. 2014). The suicide risk of gay and lesbian youth is amendable; lesbian and gay youths living in areas with school antibullying policies that did not specifically mention sexual orientation as a protected group were nearly two times more likely to have attempted suicide in the past year compared with those living in counties where more districts had these policies (Hatzenbuehler and Keyes 2013).

School-based suicide preventive interventions have shown to be effective in significantly reducing suicide attempts (Zalsman et al. 2016). Emerging research is showing that these interventions are not only efficacious, but can also be cost-effective, such as the Youth Aware of Mental Health (YAM) intervention (Ahern et al. 2018), which was presented as part of the Saving and Empowering Young Lives in Europe (SEYLE) study (Wasserman et al. 2015).

A highly increased risk of suicide after a suicide attempt can be found in people with mental disorders. To reduce risk of attempting further suicides, people with mental disorders need aftercare, especially during the first 2

years after the suicide attempt (Fleischmann et al. 2008; Tidemalm et al. 2008).

During the last 50 years, the epicentre of suicide mortality has moved eastwards from Western Europe to Eastern Europe and now to Asia (Värnik 2012). The biggest contributors to the number of suicides in the world are China and India, where half of the total suicides in the world occur, while South Korea has experienced enormous growth in suicide rates during the past decade (Vijayakumar 2004; Värnik 2012; Jeon et al. 2016).

Mental health policy

In spite of their public health impact, mental health issues were largely neglected in the international public health agenda until the 1990s. In order to successfully introduce mental health issues on the political agenda during that time, a new approach has been developed in Europe. It has been stressed that mental health cannot be reduced to an issue about mental disorders; neither the high prevalence of mental disorders, nor the need for more resources in psychiatry was used as entry points, thus, avoiding the stigma associated with mental disorders. Instead, it has been stressed that mental health is an indivisible part of public health, and that it has a significant impact on countries and their human, social, and economic capital. The aim has been to raise mental health from its professional, organizational, and even political isolation to a broader sphere of public health, that is, to shift the focus from the individual level towards strengthening the mental health approach at the population level. Acknowledging the psychosocial determinants of mental health opens the door for horizontal actions to promote population mental health (Wahlbeck 2011b, Wahlbeck 2015). Durkheim's view that social structures, promoting or hindering integration and regulation of society, have influenced the lives of individuals, and the variation in suicide rates between different groups and time periods (Condorelli 2016). Consequently, Durkheim's empirical observations and theory should be taken into consideration when shaping social policies.

It is now widely accepted that major mental health determinants are modifiable by policy actions. During the last decades, many governments and intergovernmental organizations have developed mental health policies,

as a response to increasing mental health needs in the population. Typical objectives of the policies are increased parity between mental and physical disorders, reduction of stigma, respect for human rights, a shift from hospital-based to community-based service provision and strengthening of mental healthcare capacity in primary care.

The stigma associated with mental disorders may have a negative impact on the willingness of decision-makers to commit to a high-level mental health policy. A clear public health approach, and making mental health promotion one of the core objectives, will highlight the productivity links of mental health, and offers a route to successfully avoiding the stigma and discrimination attached to mental health issues.

Mental disorders are inextricably linked to human rights issues. The stigma, discrimination, and human rights violations that individuals and families affected by mental disorders suffer are intense and pervasive. Most international mental health policy documents build on the human rights principles and stress the need for respectful treatment and empowerment of mental health service users. The United Nations Convention on the Rights of People with Disabilities (CRPD), adopted in 2006, affirms that people with mental health disabilities have the right to full participation and inclusion in society, including the right to live independently, the right to education, and the right to work. The CRPD, and related pressure from the international community, will increasingly put human and fundamental rights issues at the forefront of new regional and national mental health policies across the globe.

In May 2013, the WHO World Health Assembly approved the first WHO Action Plan on mental health, covering the period from 2013 to 2020 (WHO 2013). The plan's four major objectives are to: strengthen effective leadership and governance for mental health; provide comprehensive, integrated, and responsive mental health and social care services in community-based settings; implement strategies for promotion and prevention in mental health; and strengthen information systems, evidence, and research for mental health. The plan sets new directions for mental health, including a central role for provision of community-based care, and a greater emphasis on human rights. It also emphasizes the empowerment of people with mental disabilities, the need to develop strong civil society, and implement health promotion and prevention activities. The document proposes specific actions for Member States, the WHO, and partners. It also

proposes indicators and targets, such as a 20% increase in service coverage for severe mental disorders, and a 10% reduction of the suicide rate in countries by the year 2020, which can be used to evaluate levels of implementation, progress, and impact.

Setting mental health targets in policy action plans may help focus attention and support implementation. Targets should, however, be formulated as health equity targets to support mental health improvement and suicide reduction among the most vulnerable groups or in the most deprived areas. To be meaningful, measurement of targets should avoid masking deterioration in one segment of the population by an improvement in another segment (e.g. an increase of suicides in young people by a decrease in older people) (Wahlbeck 2009).

Stigma and public attitudes

People with mental health problems have to cope with a double problem: first, the symptoms of the mental health problem, and second, with the stigma of having a mental health problem (Rüsch et al. 2005). Stigma is a core concept in understanding the field of public mental health and provision of health services. Stigma has a strong influence on the status of mental health services, their resource allocation, and attractiveness to the workforce. It constitutes a barrier that greatly contributes to low help-seeking behaviour among people with mental health problems, and affects provision of services negatively.

Stigma and stereotypes form the public attitude towards people with mental health problems and psychiatry. Stigma related to mental health problems can be divided into: (1) perceived public stigma, that is, stereotype awareness; (2) personal stigma, that is, stereotype agreement (people's personal beliefs about mental illness); and (3) self-stigma (people's view of their own mental health problem) (Rüsch et al. 2005). Discrimination of people with mental disorders is a common manifestation of stigma.

Stigma studies across the world have generally shown consistent findings. There is a lack of parity between mental and physical disorders; people with mental disorders, as well as the services they are provided, are less valued. This is extremely unfortunate, because there are clear links

between popular understandings of mental illness and whether people in mental distress seek help or feel able to disclose their problems (Littlewood 1998; Clement et al. 2015). The core experiences of shame (to oneself or to one's family) and blame (from others) are common, although they vary between cultures. However, international studies have shown that stigma and discrimination of people with mental disorders is consistently common across cultures (Thornicroft et al. 2009; Lasalvia et al. 2013; Seeman et al. 2016). Some studies have reported higher levels of stigma tend to be found within developing countries than in developed countries (Barke et al. 2011; Semrau et al. 2015). Within Asia, compared to Western countries, people who suffer from mental illnesses are feared, considered dangerous, and should be excluded from the community. Furthermore, many studies from Asia report that mental illness symptoms are believed to have derived from supernatural forces (Lauber and Rössler 2007). Thus, the experience of mental disorders is variable between cultures.

The stigma concept can be traced back to Goffman (1963) and social interactionists, who focused on the role of social interaction in stigma, including labelling and stereotyping. This view has been challenged by theorists who focus on structural stigma and discrimination; they argue that legislation and empowering people with mental disorders will reduce stigma. Link and Phelan reconciled these different approaches in 2001 in their modified labelling theory (Link and Phelan 2001). They identify stigma as a process involving labelling, stereotyping, separation, status loss, and discrimination. They highlight structural discrimination and disadvantage, and that the following is necessary to stigmatize; social, economic, and political power.

Unfortunately, not even large-scale and expensive antistigma campaigns have shown much promise in achieving changes in public attitudes (Sartorius 2010; Henderson and Thornicroft 2013). While the Beyond Blue campaign in Australia may have led to a reduction in discrimination and stigma, it is not only difficult to determine the extent to which it has achieved, but that is has correspondingly not achieved the same degree of change as the awareness raising activities (Nous Group 2014). A combination of positive social contact with people with mental disorders, protest against stigmatizing messages and measures, and education seems to be most effective in fighting stigma. Social contact has shown to be the most promising evidence-based intervention method, including 'proxy'

contact, for example, a narrative through a film (Quinn et al. 2011; Stuart 2016). It seems to be more productive to focus on promoting positive messages and strengths rather than dispelling negative beliefs. Programmes should offer a chance to revise stereotypes through identification with ordinary people and peers. Positive models of extraordinary people with mental disorders may not have the intended effect, because they can be dismissed as exceptions to the norm. At best, antistigma activities providing social contacts are mainstreamed in school curricula and training of professionals. Awareness of mental health among young Europeans in combination with role-play activities stimulating social interactions in the classroom and increasing understanding that mental health problems can be prevented are well perceived and attractive to young people (Wasserman C. et al. 2012).

Sensational reporting and reporting with a negative undertone about mental health problems is common in the media. Many national campaigns have a network of contacts who protest against negative stories on the radio, newspapers, or television by using letters, email, and the telephone. This may be effective against reporting that people with severe mental illness are dangerous. Public protests have played a limited role in mental health campaigns compared to other civil rights movements, perhaps due to the very deeply held prejudice in society and potential for ridicule (Goldie et al. 2012).

Mental health determinants

Social, behavioural, and biological sciences have provided substantial insight into the role of risk and protective factors in the developmental pathways to mental health and mental disorders. Biological, psychological, social, and societal risk and protective factors and their interactions have been identified across the lifespan from as early as fetal life. Many of these factors are amendable and, therefore, potential targets for promotion and prevention measures. Other socioeconomic and environmental determinants for mental health problems and disorders are related to macro-issues such as poverty, lack of freedom, war, and inequity (WHO 2004).

The roots of mental health and mental disorders often lay in early life. It is well documented that poor nutrition, exposure to toxic substances such as

alcohol during pregnancy, trauma during labour, maternal depression, parental neglect, sexual abuse, other forms of trauma, and lack of stimulation can impact a child's cognitive development and socioemotional status (Richter et al. 2010; Liu et al. 2017).

Mental health and mental illnesses are determined by multiple and interacting social, psychological, and biological factors. Individual, familial, and societal determinants of mental health often lie in non-health domains such as social policy, education, and urban planning. Promising evidence has, however, indicated that effective interventions exist (Doughty 2005; Das et al. 2016): interventions in local communities (Hawkins et al. 2002), child support programmes, home visiting programmes (Olds 2002), and school programmes (Weare and Nind 2011) are some examples of effective interventions for improving mental health.

Research has, so far, mainly focused on determinants of mental ill-health, largely neglecting the need to identify both risk and protective factors. Lately, there has been a heightened interest in the determinants of positive mental health and well-being. Evidence indicates that social relationships are critical for promoting well-being and buffering against mental ill-health (Diener and Seligman 2002). This seems to be the case for people across all ages (Forsman et al. 2013; Chang et al. 2017). Although food choices are often linked to well-being in popular press, the evidence on the role of different nutritional factors is complex; thus, the direct links between eating well and feeling good remain ambiguous until more research is completed (Kirkwood et al. 2008; Lai et al. 2014; O'Neil et al. 2014). There is an increasing amount of evidence about the effects of physical exercise on mental health (Firth et al. 2015; Kvam et al. 2016). Some evidence shows that more frequent physical activity and participation in sport among adolescence contribute to greater well-being and lower levels of anxiety and depressive symptoms in both sexes (McMahon et al. 2017). Longitudinal studies provide some evidence to indicate that physical activity protects against cognitive decline in later life and the onset of depressive symptoms and anxiety (Kirkwood et al. 2008).

Mental disorders are, in the developed and developing world alike, associated with disadvantage. Many people living in vulnerable circumstances are more affected by mental health problems and die more often from suicide. The greater vulnerability of disadvantaged people to mental illnesses may be explained by such factors as the experience of

insecurity and hopelessness, rapid social change, and the risks of violence and physical ill-health.

Major individual socioeconomic risk factors for mental health problems and suicide are poverty, poor education, unemployment, high debt, social isolation, and major negative life events. Socially excluded and deprived people are at a higher risk of developing mental health problems, especially depression.

On the community level, suicides are linked with socioeconomic deprivation and unemployment (Rehkopf and Buka 2005; Middleton et al. 2006; Milner at al. 2012). In Europe, between 1970 and 2007, a more than 3% increase in national unemployment rate was linked to a 4.5% increase in suicides (Stuckler et al. 2009). Moreover, suicide attempt at a young age is a strong indicator of subsequent labour market marginalization with respect to long-term unemployment, sickness absence, and disability pension (Niederkrotenthaler et al. 2014). Immigration status has also shown to affect suicide rates; in Scandinavian studies, second- and intermediate-generation immigrants show to be at higher risk of suicide (Di Thiene et al. 2015).

The effects of paid employment on mental health are complex. On the one hand, work is a source of personal satisfaction and accomplishment, interpersonal contacts, and financial security. These are all prerequisites for good mental health. The workplace social capital (i.e. trusting relationships) has been shown to protect against mental ill-health (Oksanen et al. 2010; Gao et al. 2014). Those who become unemployed are twice as likely to have increased depressive symptoms and to be diagnosed with clinical depression compared to those who remain employed (Dooley et al. 1994). On the other hand, there is evidence indicating that a high workload, precarious work, and high emotional demand, as well as school or workplace bullying and violence, are linked with depression (Theorell et al. 2015).

Prenatal maternal stress is a risk factor for behavioural and mental disorders, including depression. Those born small, due to fetal stressors, have an increased risk of mental disorders (Wahlbeck et al. 2001; Räikkönen et al. 2008; Lahti et al. 2010), as well as of suicide completion and attempt (Mittendorfer-Rutz et al. 2004). Hostile, unstable, and unsupportive parent–child relationships can lead to depression later in life (Berg et al. 2017). Corporal punishment, harsh parenting and child abuse (physical, sexual, and emotional), temporary separation (Räikkönen et al.

2011) from parents, and interparental conflict are associated with adverse psychological outcomes (Sarchiapone et al. 2007; Afifi et al. 2014) and disorders in childhood (Madigan et al. 2007) and adolescence (Allen et al. 2007; Mills et al. 2013). Children of parents with depression are a high-risk group: six in ten will develop a mental disorder before the age of 25 (Beardslee et al. 1993). Weissman et al. (2006) found that children of depressed parents have a 3 times higher risk of developing anxiety, depression, and substance abuse disorders in comparison with non-depressed parents. Promoting a nurturing early interaction between caregivers and the child increases resilience in the face of adverse life events and promotes life-long mental health and well-being.

Substance use is a risk factor for mental disorders. Alcohol use, for instance, causes depression (Rehm et al. 2003). Alcohol problems lead to a more serious course of depression, including earlier onset of the disorder, more episodes of depression, and more suicide attempts (Sher et al. 2008). A rise in per capita alcohol consumption has been linked to a post-war rise in suicide mortality in many European countries (e.g. Denmark, France, Hungary, Norway, and Sweden), but not in southern Europe (Norström and Ramstedt 2005). The link seems to be more pronounced in countries where strong spirits dominate the consumption. There is strong evidence supporting the effectiveness of policies that regulate the alcohol market, for example, by taxation and restricting access, in reducing the harm done by alcohol (Anderson 2006; Anderson et al. 2013). A natural experiment in the former USSR during the Gorbachev rule in the second half of the 1980s, characterized not only by political reforms, but also by strict limits on the sale of alcohol and restrictive attitude towards alcohol consumption, resulted in history's most effective suicide prevention programme for men. In all 15 republics of the USSR, there was a 40% decrease in the number of suicides for men between 1984 and 1986. In comparison to a 3% decrease in 22 European countries studied during the same time (Wasserman et al. 1998). Promotion of a healthy lifestyle and avoidance of harmful drinking are cornerstones in promoting good mental health and preventing suicides.

Mental, social, and behavioural health problems interact, which may intensify their effects on behaviour and well-being. Substance abuse, violence, and abuses of women and children, on the one hand, and health problems such as heart disease, depression, and anxiety on the other, are more prevalent and more difficult to cope with in conditions of high

unemployment, low income, limited education, stressful work conditions, gender discrimination, unhealthy lifestyle, and human rights violations.

Well-being and mental health promotion

In recent years, there has been a discernible shift of focus in the field of public mental health from illness to well-being. The emergence of positive psychology, and the science of well-being, has brought with it a greater interest in establishing the underlying causes of positive mental health and well-being. Standardized measures of well-being have been used in population-based surveys (Bech et al. 2003; Tennant et al. 2007, Vaingankar et al. 2018) and there are several countries in Northwestern Europe (e.g. England, Iceland, and Scotland) that perform repeated measures of mental well-being in the population.

Mental health promotion aims to improve mental health of the population by strengthening well-being. It implies the creation of individual, social, and environmental conditions that are empowering and enable optimal health and development. Such initiatives involve individuals in the process of achieving positive mental health, well-being, and quality of life. Mental health promotion is an enabling process, done by, with, and for the people.

Common principles and recommendations for modern mental health promotion were laid by The Melbourne Charter in 2008. The Charter provides a framework that recognizes the influence of social and economic determinants on mental health and mental illness, and it identifies the contribution that diverse sectors (including but not exclusive to health) make in influencing those conditions that create or ameliorate positive mental health. The Charter stresses that mental health promotion is everybody's concern and responsibility; that mental well-being is best achieved in equitable, just, and non-violent societies; and that mental health is best promoted through respectful, participatory means where culture and cultural heritage and diversity are acknowledged and valued (Global Consortium for the Advancement of Promotion and Prevention in Mental Health 2009).

In many aspects, the promotion of mental health overlaps with prevention, yet both are distinct. The emphasis in mental health promotion is on positive mental health and well-being (what can be done to keep

people healthy or to become even healthier), rather than illness prevention (what can be done to avoid illness).

Population-based approaches for promoting mental health and well-being utilize principles of public participation, engagement, and empowerment and are implemented in everyday contexts such as in families, schools, and workplaces. Effective mental health promotion builds on cross-sectoral collaboration with non-health sectors, including education, housing, employment and industry, transport, arts, sports, urban planning, and justice.

The lessons of the successful control of infectious and cardiovascular diseases indicate that the road to improved mental health among populations lies not in the investment in of mental health services, but in promotion and prevention activities. Thus, lately many policy documents have taken the 'Health in All Policies' (HiAP) approach, which is targeting determinants of mental health across policy areas in the whole population, reaching out to public policymakers to mainstream mental health promotion and prevention of mental health problems in non-health policies. HiAP is a relatively new approach to the development, implementation, and assessment of public policies across sectors that systematically take into account the health implications of decisions. It can be seen as a strategy to recognize that mental health is greatly affected by policies in other sectors than in the health sector (Wahlbeck and Taipale 2006; Mäkinen 2009; Wahlbeck 2015). For instance, the policies in the employment sector influence unemployment and suicide rates (Dooley et al. 1994; Norström and Grönqvist 2015).

Disadvantaged and vulnerable populations have a significant need for mental health promotion action. Strengthening mental health adds to the human capital asset of vulnerable populations. The promotion of mental health can play an important role in breaking the intergenerational cycle of poverty and mental ill-health through promoting positive mental health outcomes (Petersen et al. 2010).

The concept of well-being comprises two main elements: feeling good (hedonic well-being) and functioning well (eudaimonic well-being). Happiness and enjoyment are aspects of hedonic well-being. Resilience (the capacity to cope with adversity), sense of mastery of one's life, and sense of coherence and optimism are characteristics of eudaimonic well-being (Huppert 2008).

Being in a state known as mindfulness, ‘the state of being attentive to and aware of what is taking place in the present’, has also been shown to predict positive mental states, self-regulated behaviour, and heightened self-knowledge (Brown and Ryan 2003) and may significantly improve symptoms for various mental health conditions (Gotink et al. 2015). Self-determination theory suggests that an open awareness is particularly valuable for choosing behaviours that are consistent with one’s needs, values, and interests (Ryan and Deci 2000). This self-regulatory behaviour is thought to be important for well-being.

Although the intervention research-base in mental health promotion is still developing, several effective population-level interventions have been identified (Mrazek and Haggerty 1994; Sandler at al. 2014). A large range of multifaceted outcomes from mental health promotion programmes have impacted other sectors such as education, labour and employment, and family cohesion; however, effects have often been seen after a longer follow-up time than that usually used in most standard intervention studies.

An important target for mental health promotion interventions is parenting, including early parent–child interaction and approaches to discipline in child upbringing. Programmes should address the intergenerational transmission of poor parenting; abused and neglected children are more likely to become adults who are hostile, reject parenting, and display negative discipline practices towards their own children. Parenting support practices need to focus on the positive, taking an empowering approach, and enhancing positive mother–infant and father–infant interaction and enjoyment (Stewart-Brown and Schrader-McMillan 2011).

Promoting a nurturing early interaction between caregivers and the child increases the resilience of children in the face of adverse life events and promotes life-long mental health and well-being. Home visitation programmes that provide counselling, as well as a specific intervention to strengthen parent–child interaction, have been shown to be effective when delivered by trained lay women in low- and middle-income countries (Cooper et al. 2009), and by trained nurses in high-income settings (Olds 2002). Such programmes have shown good effects, improving maternal sensitivity, and reducing intrusiveness and improving attachment of children (Cooper et al. 2009).

The past two decades have seen a significant growth of research and good practice on mental health prevention and promotion in schools (Wasserman et al. 2015; Zalsman et al. 2016; Ahern et al. 2018). Schools are an important setting for mental health promotion, through their role in helping to establish identity, interpersonal relationships, and other transferable skills. Across the world, an increasing number of schools are engaging in a wide range of mental health-related initiatives and policies, which, in many places, are showing promising results. Activities operate under a variety of headings, not only ‘mental health’, but also ‘social and emotional learning’, ‘emotional literacy’, ‘emotional intelligence’, ‘resilience’, ‘life skills’, and ‘character education’. There is growing evidence showing the effectiveness of mental health promotion in schools. Positive impacts include the reduction of depression, aggression, impulsiveness, and antisocial behaviour, as well as the development of proficiencies that promote mental health such as cooperation, resilience, a sense of optimism, empathy, and a positive and realistic self-concept. Programmes have also been shown to help prevent and reduce early sexual experience, alcohol and drug use, violence and bullying in and outside schools, to promote pro-social behaviour and, in some cases, reduce juvenile crime (Weare and Nind 2011; Sandler et al. 2014). Furthermore, mental health promotion programmes significantly improve academic performance. A meta-analysis summarized research on 213 social and emotional learning programmes and found that schools with effective programmes had an 11-percentile improvement in achievement tests, a 25-percentile improvement in social and emotional skills, and a 10 percentile decrease in classroom misbehaviour, anxiety, and depression. Data indicates that successful school programmes include those with a sequential and integrated skills curriculum, active forms of learning to promote skills, and a focus on skill development and explicit learning goals (Durlak et al. 2011). Research has also indicated that during evaluations of school-based mental health programmes, when considering student feedback, it is imperative to be conscious of power dynamics that are present between mental health professionals and pupils, as the opinions of more reserved students may become unintentionally overlooked (Wasserman C. et al. 2018). Teacher well-being is an important component of the whole-school approach to mental well-being; results of an European study (Wasserman D. et al. 2010; Carli et al. 2013) showed that psychological well-being of

teachers is linked to teachers' readiness to help pupils with mental health problems (Sisask et al. 2014).

For the adult population, the workplace is an important setting for mental health promotion. Actions can be implemented at both an organizational level within the workplace and targeted at specific individuals. The former can target managers and include measures to promote awareness of mental health and well-being in the workplace and improve managers' skills in risk-management of stress and poor mental health (Nyberg et al. 2011). This can be achieved by examining job content, working conditions, terms of employment, social relations at work, modification of the physical working environment, flexible working hours, improved employer–employee communication, and opportunities for career progression. Actions targeted at individuals can include modifying workloads, providing cognitive behavioural therapy, relaxation, and meditation training, time management training, exercise programmes, journaling, biofeedback, and goal-setting. Structuring employment to create 'good work' brings health benefits to the individual, financial benefits to the corporation, and both direct and indirect improvements to the fabric of society. Effective programmes address work context, work content, and individual resilience. Effective management styles are those that promote organizational justice, workplace support, control possibilities of the work demand, active participation of employees, and provide clear and consistent communication. Effective work content is that which protects employees from unreasonable job demands, promotes employee control and autonomy, flexible working schedules, and job stability. For individuals, effective comprehensive programmes are those that promote training in both resilience and stress management (Czabała et al. 2011).

For older people, the most promising interventions promoting mental health include social activities. Studies have shown that associations exist between social capital in the ageing population and mental health (Forsman et al. 2011b, 2012). Crucial components of the individual-level social capital concept, such as low social support and small social network size, are associated with depressive symptoms and depression, while loneliness is linked to depressive symptoms and depression. Research has highlighted that civic mistrust and lack of reciprocity or social participation (i.e. low individual-level social capital) are associated with depressive symptoms among older adults. Mental health of older adults can be strengthened by

addressing social capital. With an increasing retirement age in many countries, work may well have a protective effect for older people, but only if it is flexible enough to take into account older people's differing capabilities and needs. Data highlight the effectiveness and subjective importance of social activities in maintaining mental health and well-being among older adults. The social activities are an important mental health resource among older adults, because of the accompanied sense of belonging to a social group, as well as feelings of purpose, with regard to everyday life and hope for the future. Psychosocial interventions aiming to increase the social contacts of older participants tend to improve mental well-being, as this reduces feelings of loneliness. Systematic review and meta-analysis show that social activities among older people significantly reduced depressive symptoms when compared to no-intervention controls (Forsman et al. 2011a) and support use of social capital interventions in older population (Coll-Planas et al. 2017).

Prevention of mental disorders

Prevention of mental health problems and disorders has a long history. The early ideas of the mental hygiene movement, at the beginning of the twentieth century, were first translated into experimental activities in primary healthcare, schools, and public health practices. However, the systematic development of science-based prevention programmes and controlled studies to test the effectiveness of preventive interventions did not emerge until around 1980. Since then, the multidisciplinary field of prevention science in mental health has developed at a rapid pace, facilitated by increasing knowledge on malleable risk and protective factors, generating evidence showing that preventive interventions can influence risk and protective factors and reduce the incidence and prevalence of some mental disorders (WHO 2004) and self-destructive behaviours (Zalsman et al. 2016).

Mental disorder prevention aims at reducing occurrence, frequency, and relapses, the time spent with symptoms, or the risk for a mental illness, preventing or delaying their occurrence and decreasing their impact in the affected person, their families, and society. Recently, there has been a wider

acceptance and recognition of the importance of prevention in mental disorders.

Many of the effective preventive measures are harmonious with principles of social equity, equal opportunity, and care of vulnerable groups in society. Examples of these interventions include improving nutrition, ensuring primary education, access to the labour market, removing discrimination based on race and gender, and ensuring basic economic security. A particularly potent and unfortunately common threat to mental health is conflict and violence, both between individuals and between communities and countries. The resulting mental distress and disorders are substantial. Preventing violence requires larger societal efforts, but mental health professionals may be able to ameliorate the negative impact of these phenomena by implementing some specific preventive efforts and making humanitarian assistance more mental health friendly (WHO 2004; Wahlbeck 2015).

Prevention can be categorized in a number of ways: primary prevention focuses on addressing wider determinants across whole populations. Depending on the target group, primary prevention can be universal, selective, or indicated. Universal prevention is aimed at the general population and is beneficial for everyone in the total population. Selective prevention focuses on targeting groups at higher risk of developing a disorder. Indicated prevention targets high-risk people who are identified as having minimal, but detectable, signs or symptoms foreshadowing mental disorder or biological markers indicating predisposition for mental disorder, but who do not meet all diagnostic criteria for a disorder at that time. Secondary prevention involves early detection and intervention. Tertiary prevention involves working with those with an established disease in order to promote recovery and reduce the risk of relapse (Mrazek and Haggerty 1994; Campion et al. 2012).

It is increasingly accepted that prevention efforts will have a broader spectrum impact, not only on mental health, but also on employability, educational achievement, and social adjustment. This is due to common risk factors for mental disorders and opportunities in life. By acting on common risk factors, instead of trying to prevent specific disorders, a range of positive outcomes will be achieved.

The postnatal period is important for the mental health in mother and child. It has been repeatedly shown that children of families with parental

mental disorder have an increased risk of developing mental disorders. A range of interventions have been developed aiming to prevent transgenerational transfer by addressing risk and protective factors in children and their families. Issues addressed include the family's knowledge about mental illness, fostering psychosocial resilience in children, improving parent–child and family interactions, diminishing stigma, and increasing social network support. Some interventions target early parent–child interaction; others use a whole-family approach during childhood and early adolescence or focus on the children at risk themselves (Siegenthaler et al. 2012; Sandler et al. 2014; Lauritzen and Reedts 2015). Systematic reviews and meta-analyses indicated that the risk of mental disorders in the offspring can be reduced by 40% by preventive interventions (Siegenthaler et al. 2012).

There is strong evidence showing that improving nutrition and development in socioeconomically disadvantaged children can lead to healthy cognitive development, improved educational outcomes, and reduced risk for mental ill-health, especially for those at risk or who are living in impoverished communities. The most effective intervention models combine nutritional interventions (such as food supplementation) and growth charts with counselling and psychosocial care (e.g. warmth, attentive listening) (WHO 2004). In addition, iodine, which secures an adequate function of the thyroid, plays a key role in preventing mental and physical retardation and impairment in learning ability. A too low iodine intake during early gestation has been linked to lower verbal IQ and poorer reading ability of offspring at age 8–9 years. Iodine supplementation programmes ensure that children obtain adequate levels of iodine through iodized salt or water. Pregnant women may in addition need targeted prevention actions to ensure sufficient iodine intake (Bath et al. 2013; Velasco et al. 2018).

Bullying among youth is a significant public health problem; it is prevalent and frequently has detrimental effects. Being a victim of bullying is associated with being depressed or anxious, poor social and emotional adjustment, lower academic achievement (Hertz et al. 2013) and alcohol use (Marschall-Levesque et al. 2016). Data indicates a causal association between being a bully-victim and subsequent depression and panic disorder as well as subsequent suicide-related behaviours (Klomek et al. 2010; Copeland et al. 2013; Holt et al. 2015; Brunstein Klomek et al. 2016;

Barzilay et al. 2017). Perpetrators of bullying have also been shown to be at risk of depression and suicidal ideation (Kaltiala-Heino et al. 1999; Saluja et al. 2004) Prevention of bullying would improve mental health outcomes for many young people, and effective antibullying prevention programmes have been developed. A meta-analysis of school bullying strategies concluded that whole-school approaches that included multiple disciplines and complementary components directed at different levels of school organization more often reduced victimization and bullying than the interventions that only included classroom-level curricula or social skills groups (Vreeman and Carroll 2007).

Community systems-strengthening (Fund 2010) has its roots in the action that communities have always taken to protect and support their members. Modern approaches to community healthcare are reflected in the WHO Alma Ata declaration of 1978, and in more recent WHO work on the social determinants of health (WHO n.d.). Community systems-strengthening interventions focus on developing empowering processes and building a sense of ownership and social responsibility within community members. An example of such an intervention is the *Communities that Care* (CTC) programme, which has been implemented successfully in the United States and is currently being adopted and replicated in several developed countries. The CTC intervention activates communities to implement community violence and aggression prevention systems (Hawkins et al. 2002). The strategy helps communities use local data on risk and protective factors to identify risks and develop actions. These include interventions that operate simultaneously at multiple ecological levels: the community (e.g. mobilization, media, and policy change), the school (e.g. changing school management structures, curricula, and teaching practices), the family (e.g. parent training strategies), and the individual (e.g. social competence strategies). Evaluations at various CTC sites have indicated improvements in youth outcomes such as reduction in school problems, weapons charges, burglary, drug offences, and assault charges.

There is rich evidence showing that conduct disorders, aggression, and violence of young people can be prevented. The most successful preventive interventions to reduce the risk of aggressive behaviour and conduct disorders focus on improving the social competence and pro-social behaviour of children, parents, peers, and teachers. Universal interventions that have been shown to have a successful impact on conduct problems are

all school-based and include classroom behaviour management, enhancing child social skills, and multimodal strategies, including the involvement of parents. Classroom behaviour management programmes (e.g. *Good Behaviour Game*) attempt to help children better meet the social demands of the classroom through the overt encouragement of desired behaviours, and the discouragement of undesired behaviours. Social skills programmes (e.g. *I Can Problem Solve* or *Promoting Alternative THinking Strategies* (PATHS)) attempt to provide children with cognitive skills that may help them cope better with difficult social situations. Skills related to listening, empathy, interpersonal problem-solving, and conflict and anger management are taught in a classroom setting. Also, selective interventions designed for a variety of settings have been found to be effective in preventing conduct problems, including prenatal and/or early childhood programmes and school-or community-based programmes. Prenatal and/or early childhood programmes usually attempt to improve the skills of parents to nurture, support, and teach their children pro-social behaviour patterns and/or to develop the social skills of children. These programmes have been shown to decrease child conduct problems during adolescence, including reductions in violence and police arrests. School- or community-based programmes for selective child populations at risk have successfully targeted child social and problem-solving skills and/or parent management skills, resulting in a decrease in negative parent–child interactions and teacher ratings of conduct problems at school (Powell et al. 2007).

Recent research demonstrates that depressive episodes and anxiety disorders can be prevented in a cost-effective way and even in a cost-saving way (Cuijpers et al. 2012; Chisholm et al. 2016). Preventive interventions can reduce the incidence of new episodes of MDD by about 25%. Adding a stepped-care model to the preventive intervention may reduce the number of new episodes even more (Van't Veer-Tazelaar et al. 2009). However, it seems that a stepped-care model may only be cost-effective in some settings, depending on the willingness-to-pay (Van der Aa et al. 2017). Methods with proven effectiveness involve educational, psychotherapeutic, pharmacological, lifestyle, and nutritional interventions. School-based programmes targeting cognitive, problem-solving, and social skills of children and adolescents (e.g. *The Resourceful Adolescent Programme*) have reported a reduction in high depressive symptom levels of 50% or more a year after the intervention. Several selective interventions targeted at

coping with major life events have shown significant and long-term reduction in high levels of depressive symptoms, such as programmes for children with parental death or divorce or for unemployed adults. Indicated programmes for those with elevated levels of depressive symptoms, but no depressive disorder, have shown significant effects in reducing high levels of depressive symptoms and preventing depressive episodes. Such programmes mainly use a group format to educate people at risk in positive thinking, challenge negative thinking styles and improve problem-solving skills and have been shown to be effective in school (Clarke et al. 1995; Weersing et al. 2016; Garber et al. 2018) or primary care settings.

Anxiety disorders can successfully be prevented by strengthening emotional resilience, self-confidence, and cognitive problem-solving skills in school-aged children. Cognitive behavioural programmes (e.g. the *FRIENDS* programme) have significantly reduced the first onset of anxiety disorders in school children (WHO 2004; Stallard et al. 2014).

The evidence for the effectiveness of interventions in preventing post-traumatic stress disorder (PTSD) is limited. However, some studies show that PTSD severity can be reduced by brief preventive trauma-focused cognitive behavioural therapy (CBT) and modified prolonged exposure delivered within weeks of potential traumatic events (Birur et al. 2017). Psychological debriefing does not reduce the incidence or severity of PTSD or related psychological symptoms in civilian victims of crime, assault, or accidental trauma and should not be routinely offered (Gartlehner et al. 2013).

Several eating disorder prevention programmes have been developed and tried among children and adolescents. There is currently limited evidence in the published literature to suggest that any particular type of programme is effective in preventing eating disorders. Eating disorder prevention programmes, based on challenging the thin ideal (*The Body Project*) or promoting energy balance (the *Healthy Weight* intervention) have reduced the risk of future onset of eating disorders, but more research on their effectiveness is needed before large-scale implementation of eating disorder prevention programmes can be initiated (Stice et al. 2013; Stice et al. 2015; Akers et al. 2017).

Substance use disorders can be prevented by universal policy actions by reducing the availability of alcohol and drugs. Effective regulatory interventions include taxation, restrictions on availability, and total bans on

all forms of direct and indirect advertising. Policy interventions aimed at reducing the harm from addictive substances have led to the prevention of substance use disorders. When applied to alcohol, education and persuasion strategies usually deal with less alcohol consumption, the hazards of driving under the influence of alcohol, and related topics. Despite their good intentions, public service announcements are considered an ineffective antidote to the high-quality pro-drinking messages that appear much more frequently through paid advertisements in the mass media.

Psychoses are severe mental disorders with a peak incidence in late adolescence and early adulthood. Universal and selective interventions are not yet viable strategies in the prevention of psychoses. The indicated prevention approach and early identification and intervention present promising possibilities to reduce the burden of schizophrenia and other psychoses. Typically, there is a delay of 1–2 years between the onset of schizophrenia and initiation of treatment, due to failure in identifying psychosis, which, in many cases, may have a slow and gradual onset. A prolonged duration of untreated psychosis has been linked to worse outcome. Several population-based preventive programmes have been developed to reduce the duration of untreated psychosis. Improving community awareness and mental health literacy of the general population reduced the delays into treatment in the Norwegian *Treatment and Identification of Psychosis Study* (TIPS) and subsequent studies in Australia (Correll et al. 2010). Results in the prevention and delay of transition to psychotic disorder from high-risk state in adults, mostly involving second-generation antipsychotics and CBT, are promising and have become part of public health practice recommendations; however, there is still a call for more research to investigate the specific treatment effects (Schmidt et al. 2015).

Prevention of suicides

Public health approaches to suicide prevention have to integrate societal and cultural viewpoints with medical and psychological viewpoints to develop strategies that will save most lives in an effective and measurable way (Wasserman D. 2016).

Suicides can be prevented by public health actions and suicide prevention has consistently been shown to be highly cost-effective. Considerable evidence is available for the effectiveness of broadly applied population-level interventions, such as restriction of access to lethal means of suicide, and responsible media coverage of suicide issues (Zalsman et al. 2016).

Restricting access to lethal means has been supported by strong evidence. Firearm control legislations have been associated with reduced suicide rates. Control of analgesics, particularly with regards to distributions in smaller packaging, has shown to be beneficial in reducing suicide deaths. Suicide incidences were also reduced through restricting prescription and sale of barbiturates. Restriction on the availability of pesticides has been effective in countries where this mean of suicide is common. Construction of barriers at sites popular for jumping has been linked to reduce overall suicide by jumping by 86%, with little evidence of major substitution to other sites. Detoxification of domestic gas and the introduction of catalytic converters in cars have also shown to be effective suicide prevention methods. Part 13—Public health strategies: Controlling the access to means of suicide, ch. 74–81, from the Oxford Textbook of Suicidology and Suicide Prevention, Second edition, edited by Danuta Wasserman, 2020.

The probability of individuals attempting suicide decreases when they are precluded from implementing a preferred method. Although some individuals might seek other methods, many do not; when they do, the means chosen are less lethal and are associated with fewer deaths than when more dangerous ones are available. When a lethal method is unavailable at the moment of potential action, suicide attempts might be delayed so that, in some cases, suicidal impulses will pass without fatal effects (Yip et al. 2012; Barber and Miller 2014).

As a public health measure, means restriction has a long history; removal of the pump handle in Broad Street, London, United Kingdom, by John Snow in 1854 was an early example and a historic landmark in public health practice (Johnson 2006). Means restriction entails a community or societal action that does not depend on an individual’s intention or volition. Applied to the population as a whole, it typically affects people whose suicide risk is otherwise undetected, and who do not seek therapeutic assistance to prevent their crisis or for life-saving interventions when necessary. Removal or restriction of access to a lethal method changes the

context of a potential suicide by precluding potentially fatal actions or forcing the use of a less lethal method.

Application of universal measures for means restriction might be considered more or less intrusive by the general public, depending on the country. The resistance to restrictions and safety measures is underpinned by the common misperception that, despite data showing powerful population level effects, a seriously suicidal person will inevitably find a way to die and that all methods have roughly equal case fatalities. In order to implement means restriction, it is important to address these misunderstandings and gain community support.

Choice of suicide mean varies according to the country and even inside one country, and by age and gender (Ajdacic-Gross et al. 2008; Mars et al. 2014; Qi et al. 2014). Suicide means used also vary over time. These patterns suggest a close link to differences in the availability and lethality of specific suicide means. Due to availability of pesticides, suicides by pesticide poisoning are common in agrarian populations in Asia (Phillips and Gunnell 2009; Mew et al. 2017), whereas access to high buildings and bridges make jumping from high places a common mean of suicide in urban settings (Beautrais and Gibb 2009; Chen and Yip 2009; Chen et al. 2012).

In times of peace, most firearm-related deaths are suicides (Resnick et al. 2017). Enforcement of gun control policies (e.g. purchase restrictions, waiting times for gun purchase, higher age limits, licensing of firearm owners, safe storage precautions) lowers numbers of firearm suicides (WHO 2010). Empirical data suggest that firearm regulations, which function to reduce overall gun availability, have a significant deterrent effect on male suicide, while regulations that seek to prohibit high-risk individuals from owning firearms have a lesser effect (Rodriguez Andrés and Hempstead 2011; Anestis et al. 2015). Having a firearm in the home increases the risk of a violent death in the home; data from the United States of America showed that the risk of dying from a suicide in the home was tenfold greater for males in homes with guns than for males without guns in the home. Persons with guns in the home were 30-fold more likely to have died from suicide committed with a firearm than from one committed by using a different method (Dahlberg et al. 2004). Guns are highly lethal, require little preparation, and may be chosen over less lethal methods to commit suicide, particularly when the suicide is impulsive. Removal of firearms from people’s homes by regulatory means is desirable

and would result in a reduction of suicides, but may be difficult to achieve in countries with a strong pro-gun lobby.

Safe environments (e.g. safety doors on railway platforms, barriers on bridges, locked storage of firearms) contribute to suicide prevention. Prevention of suicide can be taken into account during the planning process or after an environment (e.g. bridges and railways) has been identified as a suicide hot-spot (Beautrais and Gibb 2009; Ladwig et al. 2009; Pirkis et al. 2015; Ueda et al. 2015; Sinyor et al. 2017).

Media depiction of suicide and suicidal behaviour can have protective effects on the general population, but detrimental effects on vulnerable populations. Decreased suicidal behaviour is associated with media blackouts and better quality reporting. There is significant evidence from around the world to indicate that highly sensationalized reporting of suicides, providing detailed descriptions of the method used, can and does lead to 'copycat' suicides, particularly if the news reports about celebrity suicides are mirrored with more attention in social media (Ueda et al. 2017). Suicide contagion is a concept from the infective disease model and assumes that suicidal behaviour may facilitate the occurrence of subsequent, similar behaviours. Imitation refers to the process that explains the occurrence of contagion. Suicide contagion has been investigated primarily in adolescent populations, revealing that up to 5% of all adolescent suicides may be the result of suicide clustering (Westerlund et al. 2009). On the other hand, responsible reporting on suicide reduces copycat suicide and has protective effects, especially among adolescents (Niederkrotenthaler and Sonneck 2007; Niederkrotenthaler et al. 2010). Liaising with media as well as using the educational internet-based systems has an important role in educating the public about depression, suicide preventive methods and responsible coverage of suicide (Westerlund and Wasserman 2009). Media guidelines for reporting suicides and monitoring of stigmatizing media reports have been linked with reduced stigmatization in the press and reduction of suicides. Such reporting guidelines can be based on recommendations set forth by the WHO (2017b).

More evidence is needed for community-based simultaneous multilevel interventions targeting primary care providers, gatekeepers, general populations, and patients with their relatives (Zalsman et al. 2016). However, improving the awareness and coping skills of the general public, gatekeepers (such as youth workers, police officers, and teachers), general

practitioners (GPs), and other healthcare professionals to identify people at risk of suicide has been shown to be an effective way to prevent suicide (Hegerl et al. 2009; Hoven et al. 2009; Zalsman et al. 2016). Responsiveness of services to the needs of individuals with suicidal behaviours is an essential component of suicide prevention. Training of GPs and other healthcare staff to identify depression and substance use problems, and provide adequate treatment has been successful in reducing suicidality and suicides (Appleby et al. 2000; Rutz 2001; Roskar et al. 2010; Zalsman et al. 2016). This method is especially useful for preventing suicides in females, as in a number of cultures females have a greater tendency than males to seek help from healthcare professionals (Hadlaczky and Wasserman 2009).

Over the last decade, evaluation studies involving school-based programmes have been of better quality. Systematic reviews indicate improved knowledge and attitudes towards suicide and three large randomized control trials showed significant effects on reducing suicide attempts and ideation (Zalsman et al. 2016). The Saving and Empowering Young Lives in Europe (SEYLE)—a multicentre, cluster-randomized controlled trial from 168 schools with 11,110 pupils in 10 European Union countries—demonstrated that Youth Aware of Mental Health Programme (YAM) was associated with a significant reduction of incident suicide attempts and severe suicidal ideation, compared with the control group (Wasserman D. et al. 2015).

Community, family, and school-based mental health interventions and programmes increase awareness about treatment possibilities, and may promote treatment acceptance, factors that are important in suicide prevention.

The evidence for selected strategies, which target subgroups with increased risk of suicide, such as people bereaved by suicide, victims of violence, physical or sexual abuse, is growing (Wasserman D. et al. 2012; Zalsman et al. 2016). The focus on high-risk groups is important, as suicide rates are higher in these groups compared with the general population.

Indicated prevention using various psychiatric treatments has very well documented effects in suicide prevention (Wasserman D. et al. 2012; Zalsman et al. 2016). The pharmacological treatment of psychiatric disorders, such as depressive disorders, psychotic disorders, and substance use disorders, is proven to be substantial in the prevention of suicide.

Antidepressants have been associated with reduced suicide risk; however, in children and adolescence, antidepressants have been linked to increased suicide thoughts, yet they need to be considered, since there is an increased risk of suicide with untreated depression. Psychotherapies for individuals with mood disorders have also shown to be efficacious in reducing the risk of suicide.

Combination of pharmacological treatment with psychotherapies (such as cognitive behaviour therapy, dialectical behavioural therapy, interpersonal therapy, problem-solving therapy, etc.), as well as outreach, are effective and recommended in suicide prevention. Follow-up of people who attempt suicide has found strong support (Fleischmann et al. 2008), as well has the availability of mental health services (Pitt et al. 2013).

In spite of the fact that universal approaches hold the potential to prevent a greater number of deaths (Pitman and Caine 2012), it is important that they go hand-in-hand with selected and indicated strategies, which diminish suffering for the individuals and their families.

Mental health services

Design, management, and evaluation of mental health services are a core task of public mental health. Today, mental health service provision is in a global transition from hospital-based systems to community-based systems. The change reflects the growing evidence of what constitutes cost-effective care; it also acknowledges the failures concerning issues of social inclusion and human rights of the care systems, which were based on the old-fashioned and remote institutions (asylums).

The recent history of mental health services in economically developed countries can be seen in terms of three periods: first, the rise of the asylum; second, the decline of the asylum; and third, balancing mental health services (Table 8.7.1).

Table 8.7.1 The key characteristics of the three periods in the historical development of mental health systems of care

Period 1: the rise of the asylum	Period 2: the decline of the asylum	Period 3: balancing mental services
Asylums built	Asylums neglected	Asylums replaced by smaller facilities
Increasing number of hospital beds	Decreasing number of hospital beds	Decrease in the number of beds slows down
Reduced role for the family	Increasing but not fully recognized role of the family	Importance of families increasingly recognized, in terms of care given, therapeutic potential, the burden carried, and as a political lobbying group
Public investment in institutions	Public disinvestment in mental health services	Increasing private investment in treatment and care and focus in public sector on cost-effectiveness and cost containment
Staff: doctors and nurses only	Clinical psychologist, occupational therapist, and social worker disciplines evolve	More community-based staff and emphasis on multidisciplinary team working
	Effective treatments emerge, beginning of treatment evaluation and of standardized diagnostic systems, growing influence of individual and group psychotherapy	Emergence of 'evidence-based' psychiatry in relation to pharmacological, social, and psychological treatments
Primacy of containment overtreatment	Focus on pharmacological control and social rehabilitation, less disabled patients discharged from asylums	Emergence of concern about balance between control of patients and their independence

Source: data from Thornicroft G, and Tansella M (2002). 'Balancing community-based and hospital-based mental health care.' *World Psychiatry*, 1(2):, pp. 84–90, Copyright © 2002.

A modern mental healthcare system is based on balanced care, that is, it includes both modern community-based and modern hospital-based care. In balanced care, the focus is on services that are provided in normal community settings, as close to the population served as possible, and to which admissions to psychiatric wards in a general hospital can be arranged

promptly, but only when necessary (Thornicroft and Tansella 1999, 2002; Gaebel et al. 2012).

A health policy supporting the integration of health and social services, and the mainstreaming of mental health services into primary care, improves access to care. Integrating mental health services into general healthcare is the most viable way of implementing balanced care, closing the treatment gap, and ensuring that people get the care they need. Because of the high prevalence of mental disorders, only complex and/or severe cases should be treated by specialized mental healthcare. To achieve this consistently, the services need to identify priority groups who should receive access to specialist care from among the 25% of the whole population who suffer from a mental disorder in any given year. Well targeted services are those in which specialist care concentrates on providing direct services to people with the most severe degree of symptoms and disability. Primary care responsibility for common mental health disorders should be supported by accessible referral systems and specialist supervision (Tansella and Thornicroft 1999). Providing even minimal psychotherapy in primary care can prevent full-blown depression (Smit et al. 2006). Programmes aimed at education of primary care physicians have improved the detection of depression and even led to a decrease in suicides due to depression (Rutz 2001). The use of new media, such as e-mental health and smart phone technologies, and the use of lay health counsellors, may boost dissemination of mental health interventions, especially in low- and middle-income countries.

Another cornerstone of a balanced care system is the provision of safe and high-quality home and community-based specialist services. Any developed mental healthcare system encompasses specialized community services for children and adolescents. A modern mental health system includes crisis resolution teams, home treatment, assertive outreach, and early intervention teams, day treatment facilities, and supported work. Collated evidence suggests that supported employment schemes, which consist of arranging early placement in normal work with variable support from staff, may offer better outcomes than sheltered or transitional employment approaches. People suffering from mental disorders who want to work should be offered the option of supported employment as part of their treatment package. Current evidence indicates that supported work improves clinical outcomes and supports social inclusion of people with

severe mental disorders (Crowther et al. 2001; Bruns et al. 2007; Luciano et al. 2014).

In diversified modern mental healthcare systems, particular attention needs to be paid to maintaining high-quality communication between all parts of the care system. There is a need to address three types of interfaces: (1) those within the mental health service, between its components; (2) those within the health service, between mental health and other services (both primary and secondary care); and (3) those between health and other public services, including social services and housing departments.

Available evidence indicates that community-based and diversified mental health systems, with a wide range of services, are superior to hospital-centred mental health systems, according to a range of outcomes. For instance, community-based, well-developed, and multifaceted mental health services have been linked with lower suicide rates than hospital-based traditional services (Pirkola et al. 2009). Discharged patients benefit from well-developed community care; community follow-up within 7 days of psychiatric discharge has shown a significant reduction in suicides among recently discharged psychiatric patients (While et al. 2012). Additionally, research has demonstrated that brief information interventions combined with long-term follow-up after suicide attempts have a significant influence on preventing subsequent deaths from suicide, in comparison with treatment as usual (Fleischmann et al. 2008).

A core element of modern mental healthcare is the empowerment of service users and informal carers. Historically, people with mental health problems have lacked a voice. Empowerment translates into being treated with dignity and respect in mental health services and participation of users and carers in decisions. Data suggest that the possibility to exercise control and influence leads to positive mental health outcomes. These outcomes include increased emotional well-being, independence, motivation to participate, and more effective coping strategies. Key issues that users and carers have expressed to be important to advocate for are the rights to autonomy and self-determination, to acceptable and accessible services, user-led evaluation of services, the right for everyone to be recognized as a person before the law without discrimination, the de-stigmatization of mental disorders, and more inclusive and respectful services with user and carer involvement (WHO 2005). Increased used of peer support and ‘experts by experience’ in the provision of mental health services will

support empowerment of service users and improve services (Pitt et al. 2013).

Development of mental health service systems requires access to reliable data on both mental health services and trends in mental health service provisions. International benchmarking, based on comparable data, is an important moving force for the development of mental health services in countries. Unfortunately, mental health information systems, in most countries, are geared towards hospital data, which are of less interest when developing a community-based mental health service provision system. Many highly relevant aspects of modern service provision, such as patient choice, service user empowerment, and respect for human rights, are hardly ever covered by health information systems (Wahlbeck 2011a). Additionally, in many low- and middle-income countries, there are limited mental health resources and activities, which are unequally distributed and inefficiently used (WHO 2009).

In conclusion, sufficient evidence supports effective public mental health measures to prevent suicidal behaviours. Therefore, the implementation of evidence-based strategies should be the responsibility of public health policymakers and organizations responsible for implementation.

ACKNOWLEDGEMENTS

The authors thank Daniel Ventus and Tony Durkee for assistance in preparing the text of the previous version of this chapter, along with Iva Tadic and Danielle Stone for assisting with updating the current version.

Dental public health

Amira S. Mohamed and Peter G. Robinson

Introduction to dental public health

Poor oral health is a major public health problem. The considerable burden of oral disease at a societal level reflects the cumulative impact of many people affected to a modest degree. Oral diseases are exceedingly widespread. Their impact on individuals and the community are significant, ranging from mortality to effects on general health and quality of life, and in terms of direct costs and lost productivity.

The scope of dental public health

Dental public health is the science and art of preventing oral disease, promoting oral health, and improving the quality of life through the organized efforts of society.

Major areas of dental public health activity include:

Oral health surveillance.
Assessing the evidence on oral health and dental interventions, programmes, and services.
Policy and strategy development, and implementation.
Strategic leadership and collaborative working for health.
Oral health improvement.
Health and public protection.
Developing and monitoring quality dental services.
Dental public health intelligence.
Academic dental public health.
Role within health services.

In some countries the specialty also involves providing services to special population subgroups.

This chapter reviews the epidemiology, aetiology, and management of the four oral conditions of greatest public health importance: dental caries, periodontal diseases, oral cancer, and orofacial trauma. Approaches to oral health improvement are then outlined using the framework of the Commission on the Social Determinants of Health. Finally, we consider future developments in population oral health.

Oral diseases of public health importance

Dental caries

Dental caries is the demineralization of tooth substance by acid metabolites of oral bacteria. In the very early stages, the lesion appears as a chalky white spot. If the lesion progresses, the surface of the tooth breaks down leading to cavitation. If the caries reaches the underlying dentine, it can spread more readily through this porous and less mineralized tissue towards the pulp. Infection of the pulp may allow the passage of bacteria along the root canals to the alveolar bone.

The direct consequences of this process are destruction of the tooth, pain, and a possible dental abscess. When dentine is exposed by cavitation, there may be transient pain associated with hot or cold drinks or sweet foods. Later, as the pulp becomes inflamed, the discomfort may be spontaneous, exquisitely painful, and of longer duration. In a dental abscess, pressure to the tooth is transmitted to the infected alveolus and the affected person avoids biting or knocking the tooth.

Risk factors

Four factors are necessary for caries development: dietary sugars, a susceptible tooth surface, the microflora of dental plaque, and adequate time. Dental plaque that forms on the tooth surface comprises mainly bacteria, particularly *Streptococcus mutans*, which metabolize sugars to produce acids. The acids cause demineralization of the tooth structure. With each exposure to sugar, the plaque pH falls sharply and rises slowly back to

normal levels over the following hour. Hence, caries incidence is related to the frequency of sugar intake.

At high pH, there is remineralization of the tooth, especially in the presence of fluoride. Saliva plays a crucial protective role against caries by simple dilution, buffering plaque acid, and acting as a source of minerals and immunological plaque inhibitory factors. For these reasons, dental caries is more frequent in the sites less accessible to saliva as the pits and fissures of posterior teeth and between these teeth and also in people with restricted salivary flow.

Epidemiology

Caries of the permanent dentition is traditionally measured by the number of decayed, missing, and filled teeth (the DMFT index). While, the dft index is used for deciduous teeth due to difficulty in differentiation between the naturally exfoliated teeth and missing teeth due to caries. For more precision, the number of surfaces affected can be recorded (DMFS, dfs). The index aggregates both disease and treatment experience, hence it is affected by treatment decisions of dentists and is less valid with increasing age. Since each of the categories is equally weighted, it is insensitive to both the severity of the disease and outcomes of treatment. Nonetheless, the DMFT index, having been used for almost 80 years, will continue to be used for some time. In addition to the assessment of the prevalence of caries, its impact is now routinely measured, most frequently by measures of oral health-related quality of life.

Typically, the pattern has been of high caries levels in developed countries associated with exposure to sugars. In the mid-1970s, DMF levels in 12 years old began to fall dramatically in many developed countries such as the United States and European high-income countries, with less obvious decreases in low-income countries (Kassebaum et al. 2017). National surveys in United Kingdom over 40 years (1973–2013) showed that the prevalence of obvious cavitation (caries in dentin) decreased gradually from 72% to 26% from 1973 till 2013 in 5-year-old children. Similarly, 15-year-old children showed a fall in obvious caries prevalence from 97% in 1973 to 42% in 2013 (Murray et al. 2015). The National Health and Nutrition Examination Survey (NHANES) in 2011–2012 also showed a decrease in caries in primary teeth and to a lower extend in permanent teeth in

comparison to 1999–2004 (Dye et al. 2007). This decrease can be attributed to greater availability of fluoride, changing diagnostic behaviours, and greater access to care in some countries.

Aggregate national data on caries levels are useful, but mask important trends, particularly inequalities in oral health. When disease prevalence was high, disease was almost universal and inequalities were manifest as differences in the numbers of teeth affected in individuals. With lower disease prevalence, the distribution is highly skewed with typically 20–25% of the population having moderate or severe caries (more than three teeth affected) and the majority having no obvious caries. This affected minority tends to be those living in the most deprived areas. Furthermore, dental caries has less impact on the lives of children and older adults from high-income environments than those from low-income environments. These findings reinforce the importance of measuring both the disease impact and prevalence. Based on the World Health Organization (WHO) databank data from 2000 to 2015, the median of mean DMF in 12-year-old children ranged from 0.9 in low-income countries to 2.1 in upper-middle countries (Frencken et al. 2017).

Although data are scarce, there are concerns with the rising caries levels in children in some countries undergoing economic growth and nutritional transition. For example, dental caries is very common and severe in 12-year-old children from several Asian and South American countries but remains relatively low in most African countries where poor economic growth restricts sugar consumption. Here again, national data may mask local variations, particularly high caries levels in urban areas.

When estimating the burden of dental caries, untreated caries is more relevant than treated caries. In 2015, the age-standardized prevalence of untreated caries was estimated to be 34.1% in permanent teeth, affecting 2.5 billion people and 7.8% in deciduous teeth, affecting 573 million people worldwide (Kassebaum et al. 2017).

Management

Until the nineteenth century, tooth extraction was the only useful treatment for dental caries. Treatment evolved to restorative care in which the infected parts of the tooth are removed and replaced with an inert obturating filling, for example, dental amalgam. During the latter half of the twentieth century,

in developed countries, operative treatment for adults has become increasingly complex and technology intensive. Badly decayed teeth can now be restored with a range of adhesive tooth-coloured materials that are either formed in the mouth or prepared in laboratories and then fitted. Originally, missing teeth could only be replaced with removable dentures. Now they can be replaced with bridges or prostheses supported by osseointegrated implants that project out through the gingivae.

In developing countries, the necessary infrastructure is often not available for complex treatment of carious teeth. In some areas, atraumatic restorative treatment (ART) is the only sustainable method because the decay is removed with hand instruments and the cavities filled with glass-ionomer cements. The instruments are easily portable and treatment can be provided painlessly, at low cost, without local anaesthesia, electricity, or expensive dental equipment. Systematic reviews have shown the effectiveness of the ART approach (Duangthip et al. 2017).

Implications of changes in caries prevalence

At the low disease prevalence in the developed world, proportionately more caries affects the accessible occlusal surfaces of the teeth. Fissure sealants can be applied to these surfaces to prevent caries and are cost-effective at low caries levels. Only simple restorations are needed to treat existing disease at these sites. The disease also progresses more slowly, so allowing deferred operative treatment. Many lesions are detected at an earlier stage so that new dental materials can be used in minimally invasive techniques. Minimal intervention dentistry is a new approach that aims to preserve dental tissue by integrating caries prevention, remineralization of demineralized enamel and dentine, and conservative placement and replacement of restorations.

Increasing the intervals between dental examinations is safe and effective for children and adults with low disease incidence. There is greater scope to employ dental care professionals (DCPs), other than dentists, who can also deliver effective preventive interventions such as fluoride varnish. However, because of the skewed distribution of dental caries, there remains a minority with high levels of caries to be managed.

There is also a large cohort of people more than 50 years old who have experienced severe dental caries and cycles of re-restoration. This so-called

heavy metal generation (Fig. 8.8.1) will continue to need complex and specialized treatment for decades to come, with high expectations of retaining their natural dentition into older age. By contrast, the needs of younger people are likely to be more straightforward. The proportion of dental treatment that falls within this straightforward category will continue to grow and can be delegated to other DCPs, especially in deprived communities, hence liberating dentists' time to undertake more complex treatments.

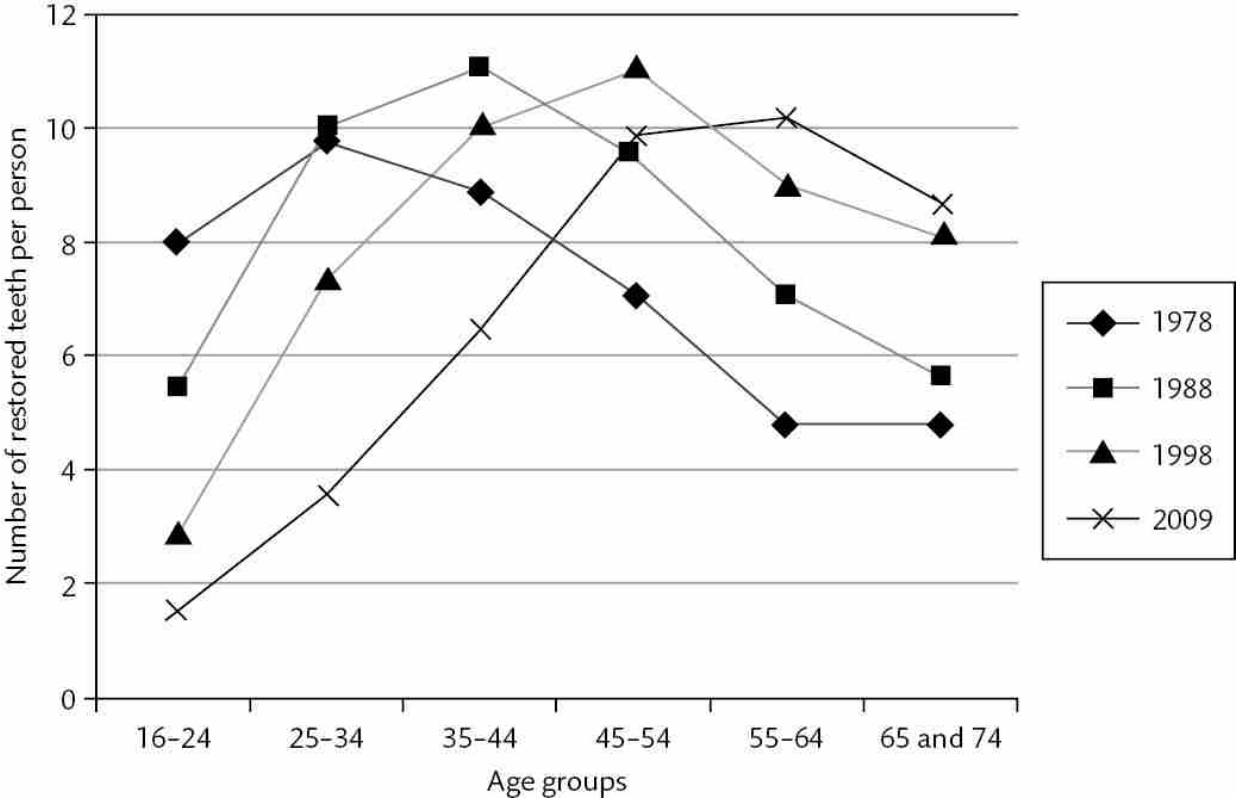

Fig. 8.8.1 The 'heavy metal' cohort.

Periodontal diseases

Periodontal diseases comprise a range of inflammatory diseases of the periodontium: the attachment between gingivae and tooth. In gingivitis, the attachment remains in its original position, whereas periodontitis is defined by migration of the epithelial attachment which reduces the amount of periodontal ligament and bone supporting the tooth.

Gingivitis, which is exceedingly common, is an inflammatory response to plaque. Along with redness and swelling, the gums may bleed on gentle provocation, such as tooth brushing. Pain is uncommon. Systemic involvement including hormonal changes, skin diseases, and medication use may modify these diseases or cause other gingival changes. In periodontitis, the loss of periodontal attachment deepens of the pockets between the gingivae and teeth and by recession of the gingivae. In severe cases, the supporting structures are so depleted that the teeth become loose. The disease is rarely painful unless an acute infection complicates a periodontal pocket (‘a lateral periodontal abscess’) or if the exposed root surfaces are temperature sensitive.

Periodontitis has been consistently linked with psychological and social consequences on everyday life, which intervention studies indicate is reduced by treatment. More severe and untreated disease results in the loss of teeth and the need for additional treatment to replace them.

Another periodontal disease of public health importance is acute necrotizing ulcerative gingivitis (ANUG or ‘trenchmouth’), which causes necrosis, ulceration, soreness, and bleeding of the gingivae. The ulcerated papillae may have a grey slough, and there may be a characteristic foetor. Lymphadenopathy, and mild fever are variable findings. In severe cases, necrosis may extend over adjacent tissues to cause gross destruction of oral, and facial tissues (known as cancrum oris or noma).

Pathogenesis

The pathogenesis of periodontitis involves the interaction of plaque pathogens with the host’s immune system. Considerable research is devoted to determining which, if any, specific pathogens are responsible for periodontal destruction (the ‘specific plaque hypothesis’). Dental plaque is ubiquitous, but destructive disease occurs only in a minority of people. Apart from plaque, there are important determinants of periodontal disease susceptibility.

It is now clear that tobacco exerts a powerful independent deleterious effect. Periodontal treatment is also less effective in smokers, meanwhile smoking cession can have a positive impact on the periodontium (Alexandridi et al. 2018). Stress is another risk factor: for example, greater occupational stress is associated with progression of periodontitis. ANUG has been noted among soldiers on difficult postings, students during exam terms, and in people experiencing negative life events.

Periodontitis often takes decades to become clinically detectable. While it is more common and severe with advanced years, periodontitis is not a consequence of age. It is associated with poor oral hygiene and does not progress in adults with good oral hygiene.

Epidemiology

Gingivitis affects almost half of the 15-year old children and its prevalence has remained stable through the UK national surveys over 40 years (Murray et al. 2015). Mild periodontal pocketing is common, being seen in approximately half of UK and 63% of US adults (White et al. 2011; Eke et al. 2012). Severe periodontitis is much less frequent. Lost attachment or pockets of 6 mm or more (thought to be sufficient to threaten tooth survival) are seen in 9% of UK and 25% of US adults. These apparent differences between countries may be in part attributed to different survey methods. In 2015, the age-standardized prevalence of severe periodontitis globally was 7.4% (affecting 538 million), with no sex difference in incidence (Kassebaum et al. 2017). The disease is more frequent and severe in countries where tooth cleaning practices are less sophisticated

In many developed countries, ANUG is a disease of young adults. There are no good incidence data, but anecdotally, it has become less frequent among developed populations in recent years. A variant of the disease is associated with HIV infection. ANUG is also seen in children in developing countries where it can progress in the absence of treatment.

Management

For most people, the progression of periodontal destruction is compatible with the retention of a natural dentition into old age. A significant minority of people may lose teeth from periodontal diseases and considerable effort is

spent by dental professionals to prevent and treat them, primarily by mechanically removing plaque through regular toothbrushing and flossing of teeth. Adjunctive treatments include removal of calcified plaque (calculus), planing away the superficial layers of the roots and periodontal surgery in severe cases.

Systematic reviews are beginning to provide an evidence base for periodontal therapy although there may be considerable Hawthorne effects reflecting differences between the effectiveness of treatment provided routinely in primary care and its efficacy in clinical trials conducted in university departments. There are also few long-term studies showing effects on tooth retention. A metanalysis showed that powered toothbrushes caused more reduction in plaque and gingivitis on both short term and long term (more than 3 months) if compared with the manual brushes (Yaacob et al. 2014). The most common professional procedure to prevent and treat periodontal diseases is removal of calculus by scaling and polishing. Evidence of low to moderate strength shows its effectiveness in improving measures of dental plaque and gingivitis especially if combined with oral hygiene instruction. There is no compelling evidence of benefits from professional mechanical plaque removal alone over simple oral hygiene instruction to prevent periodontal diseases. However, repeated oral hygiene instructions appear as beneficial as repeated professional mechanical plaque removal (Needleman et al. 2005, 2015). Non-surgical periodontal debridement is the gold standard for management of periodontal disease and provides similar levels of reduction and maintenance of pocket depth as surgical treatment especially in case of pockets of shallow or moderate depths. While it is less effective in the initial pocket reduction than surgical treatment in case of deep pockets. The use of systemic antibiotics can add a small benefit to the treatment outcomes (Drisko 2014).

Oral cancer

Benign oral cavity neoplasms include papillomas, polyps, and various types of granuloma. This subsection will deal principally with malignant oral neoplasms, of which approximately 90% are squamous cell carcinomas. They may occur on the lip, tongue, gingivae, oral floor, or elsewhere in the mouth (Some statistics on mouth cancer also include the pharynx). The site is often related to the aetiological factors. Lesions may present as swellings,

ulcers, or red, white patches, and many are painless until they become large. Malignant change can occur in a number of lesions which precede tumour development and present as white or red patches of unknown origin. Malignant change is also occasionally seen in oral lichen planus and hyperplastic candidiasis.

Risk factors

Cancer of the lower lip is strongly associated with sunlight exposure, especially in fair-skinned people. Tobacco use, whether chewed or smoked, predisposes to intraoral cancer. The high incidence of oral cancer among southern Asians is in part due to the addition of tobacco to betel quid or 'paan'. There are dose–response relationships for the duration of use and type of tobacco inhaled. Oral cancer risk in current smokers is three times higher than non-smokers. The risk in-ex smokers is lower than in current smokers (Gandini et al. 2008). Alcohol has additive effects with tobacco use while it may have an inverse association with oral cancer in absence of smoking and betel quid chewing (Globocan 2010; Petti et al. 2013). Other risk factors include human papillomavirus (HR-HPV) types (HPV16 and HPV18) and nutritional deficiency (Shield et al. 2017). HPV-associated tumours show a predilection for the tonsils and oropharynx and although apparently aggressive, carry a better prognosis.

In the past, oral cancer occurred mainly in older people (over 60 years). However, the incidence is increasing in developed countries because of a rising incidence in people younger than 45 years, where oral cancer may be a distinct form related to human papilloma virus (HPV) and associated with vaginal and oral sex. Higher risk of head and neck cancer is associated with lower levels of income and education, a difference not totally explained by smoking, alcohol drinking, and diet (Conway et al. 2015).

Epidemiology

Oral cancer is the eighth most common cancer worldwide. More than 450,000 people globally are diagnosed each year with oral and/or pharyngeal cancers (Crall and Forrest 2018). Lip, oral, and pharyngeal cancers represent 3.8% of all cancer cases and cause 3.6% of cancer deaths (Shield et al.

2017). Oral cancer is characterized by late diagnosis and a low 5-year survival rate of 50% worldwide (Gupta et al. 2016)

The incidence is increasing in some Western European countries. The highest reported incidence rates are in South Asian Countries like India, Srilanka, Pakistan, and Bangladesh, where oral cancer is the most prevalent cancer, representing one-quarter of all new cases of cancer (Gupta et al. 2016)

In 2015, the estimated age-standardized incidence rate of mouth and lip cancer per 100,000 population worldwide is 8.1 for males and 4.1 for females. The age-standardized death rate per 100 000 population among males is 3.1 which is also higher than in females (1.4) (Global Burden of Disease Cancer Collaboration 2017).

Management

As early intervention improves oral cancer survival and many cases are preceded by premalignant lesions, case finding would seem useful for disease control. In a 15-year follow-up study in India, oral cancer mortality rate was not significantly different between screened and unscreened groups while among tobacco and alcohol drinkers, the screened individuals had a significantly lower mortality rate than unscreened (Sankaranarayanan et al. 2013). However, there is still no strong evidence to justify active screening in countries with a lower prevalence and available dental services. Opportunistic screening as part of routine dental visits may be viable.

Trauma

Trauma to the teeth is common and frequently causes fracture of the tooth or supporting bone or bodily movement of the tooth including complete avulsion. In many cases, the long-term survival of the tooth is threatened. As the anterior and most visible teeth are most often involved, the result can be disfiguring.

Risk factors

Main causes are falls (31.7 to 64.2%), sport activities (up to 40.2%), bicycling accidents (up to 19.5%), traffic accidents (up to 7.8%), and

physical violence (up to 6.6%) Protruding upper front teeth and inadequate lip coverage also put individuals at risk (Zaleckiene et al. 2014).

Epidemiology

Worldwide, the prevalence of dentofacial trauma experience is approximately 10–15%. The experience of traumatic dental injuries among schoolchildren aged 12–15 years varies between 14.4 and 33.8%. The peak age for trauma is early adolescence, with boys experiencing more injuries than girls. The prevalence of dental injuries in permanent teeth (58.6%) is higher than that in primary teeth (36.8%). Tooth displacement (Luxation) is more common in primary teeth as the supporting bone is less mineralized while tooth fracture is more common in permanent teeth (Zaleckiene et al. 2014).

Management

Trauma to the deciduous teeth is managed by monitoring, in case any consequent infection threatens the permanent tooth developing beneath it. In permanent teeth, adhesive fillings can be used to protect sensitive fractured teeth and dressings (usually calcium hydroxide) to allow continued root development in immature teeth. Permanent teeth that have been knocked out, should be replaced in the socket as soon as possible or placed in a suitable container of milk or normal saline. Dental care should be sought immediately as tooth replantation within 30 minutes provides the best long-term survival of avulsed teeth. The tooth should be splinted to adjacent teeth for 7–14 days and antibiotic and antitetanus treatments given.

The treatment of dental trauma, especially luxation injuries is expensive, time-consuming, and involves different specialists. In the United Kingdom, the average total cost of treating one patient with a dental traumatic injury has been estimated at US$1,665 (Wong and Kolokotsa 2004). In Denmark, annual cost of treatment is estimated to be US $2–$5 million per 1 million inhabitants (Andersson 2013).

Impacts of oral disease

In addition to mortality, oral disease affects other aspects of general health. Limited dietary choice and calorific and micronutrient intake are direct consequences of conditions such as dry mouth, poorly fitting dentures, and loss of teeth. Early childhood caries limits growth and development at the most important stage of life.

Oral diseases also directly affect quality of life. Dental pain is very common. In the United Kingdom, 12-month prevalence of oral pain ranges from 8% to 40.4% which leads to functional limitation and disability (Joury et al. 2018). Even the appearance of the mouth is hugely important, affecting self-esteem and willingness to interact with others. People with visible dental disease are judged by others to be less socially and intellectually competent and less well psychologically adjusted. Good dental appearance is regarded as a requirement for some prestigious occupations.

Considerable effort has been made to assess the extent to which oral disorders compromise aspects of daily life. This research is beginning to reveal the determinants of these impacts. In turn, that information is being used to prioritize resources, to suggest avenues for action, and to evaluate interventions.

Global burden of oral diseases

Despite the relative stability in age-standardized prevalence of oral disease from 1990 to 2015, the number of untreated cases of oral disease increased from 2.5 billion to 3.5 billion due to population growth and ageing (Kassebaum et al. 2017).

Direct costs are incurred from the treatment of oral disease as well as the costs of other conditions caused or exacerbated by oral disease. Globally, the direct cost for treating oral diseases in 2010 was around US$298 billion, which constituted about 4.6% of global health expenditure (Kassebaum et al. 2017). In 2015, the direct treatment costs reached $356.80 billion. The highest expenditures were in high-income north America followed by Western Europe. The cost of the Western model of dental treatment would exceed total national healthcare expenditure in many developing countries.

Indirect costs might include reduced employment or promotion expectations and opportunities, limitation of academic achievement, and the loss of economic productivity. In Australia, 1.1 million work days and 600,000 school days are lost yearly (Richardson and Richardson 2011).

Low-income families are more likely to lose time from work and school because of dental disease, hence compounding the inequalities that already exist in health, income, and educational attainment. Worldwide, the total productivity loss associated with oral diseases was $187.61 billion in 2015. Severe tooth loss was the main reason responsible for $126.67 billion (67%) followed by severe periodontitis ($38.85 billion, 21%). Untreated caries in permanent and deciduous teeth was responsible for $21.19 billion (11%) and $0.90 billion (0.5%), respectively. Western Europe and North America had the highest productivity losses. Cumulatively, the direct and indirect costs of dental diseases form a total global cost of $544.41 billion in 2015 (Righolt et al. 2018).

Links with other diseases

Many associations between oral conditions and general health have been proposed in the last two decades. Periodontal diseases have been linked to cardiovascular diseases, diabetes, stroke, pre-term birth, and low birth weight. Some authors have even suggested that periodontal diseases are independent risk factors for these diseases or claimed that specific cardiovascular risk factors such as tobacco use, obesity, and lower serum high-density lipoprotein cholesterol are more common among people with high dental disease experience. Some, such as tobacco smoking, are independent risk factors for both cardiovascular and periodontal diseases.

Poor oral hygiene predicted cardiovascular outcomes among Scottish adults, although the nature of the relationship was not determined. Having fewer teeth and not wearing dentures prospectively predicted the incidence of falls among Japanese elders. Relationships between oral health and all-cause mortality are partly explained by covariates but persist after many of these covariates have been accounted for (Sabbah et al. 2013).

Systematic and narrative reviews of these associations have not yielded firm conclusions because of methodological complexity. For the time being, we assume these relationships are confounded by environmental and lifestyle factors common to both sets of diseases. The existing evidence suggests that interventions improving periodontal health do not modify these other health problems. However, these epidemiological associations between oral and general health are compatible with the strategy of targeted interventions which could adopt a common risk factor approach (CRFA),

tackling risk factors that are common to many conditions. The CRFA was anticipated to provide multiple benefits, reduce duplication, save resources, improve effectiveness, and reduce social inequalities. However, a recent concern with the CRFA is 'lifestyle drift' where the focus has been on behaviours rather than their upstream structural, social, and psychological determinants. This recognition of the social context in which personal choices are made avoids the social iatrogenesis of describing oral health in individual terms.

Oral health programmes should be closely integrated into programmes to improve general health for the whole population and for specific groups such as older people (Satur et al. 2010). Similar observations have been made about global health policy where a focus on single diseases has ignored the problems of people experiencing multiple health problems and reinforced health inequalities.

Inequalities in oral health

Inequalities occur in the distribution of almost all oral conditions and this area of research has grown in parallel with the interest in health inequalities, led by the Commission for the Social Determinants of Health (CSDH 2008). The resultant formation of the Global Oral Health Inequalities Research Agenda (Sgan-Cohen et al. 2013) of the International Association of Dental Research will add impetus and hopefully, practicable policies.

Oral health inequalities are related to socioeconomic status, ethnicity, or region, both in gradients and in fine grain. Whether socioeconomic status is measured by education, occupation, or income, these inequalities consistently relate to the degree of social inequality and not just the distribution of resources. Differences in oral health by ethnicity and family deprivation were found among British children but were less evident among adolescents. However, differences by residential deprivation were greater among adolescents, which indicates the importance of investigating the effect of socioeconomic disadvantage using multiple measures (Rouxel and Chandola 2018). Furthermore, levels of total tooth loss across the United States are related to the level of income inequality within each state and not just absolute levels of poverty (Bernabé and Marcenes 2011).

There are social gradients for oral cancer incidence (Johnson et al. 2011), tooth loss (Tsakos et al. 2011), total absence of teeth, presence of untreated

decay or the presence of a filled tooth (Elani et al. 2012), severe periodontitis (Eke et al. 2012), pain caused by untreated oral conditions (Joury et al. 2018), self-rated oral health, and oral impacts (Tsakos et al. 2011). Periodontal diseases are unusual in childhood and yet have been linked to the structural determinants of health more strongly than to individual factors among Brazilian 12-year-olds (Jordao et al. 2012).

The life course approach indicates how people's circumstances in early life, accumulate to influence their health throughout life. Long-term follow-up of birth cohorts confirms the importance of this accumulated effect. In one study, 5-year-olds of low socioeconomic status had more decay, more fillings, and worse periodontitis and were more likely to have had a tooth extracted at the age of 26 years, even after controlling for childhood oral health. Furthermore, changes in socioeconomic status throughout life were associated with differing levels of oral health in adulthood (Thomson et al. 2004).

Reducing oral health inequalities

Greater concern about inequalities in health has had a number of broader implications. Earlier understanding had seen such factors as general socioeconomic, cultural, and environmental conditions, and consequently people's living and working conditions as the upstream determinants of *health*. More radical models look even further these upstream factors to consider the social determinants of health inequalities (Krieger 2008). From this perspective, the social determinants of health arise and are sustained by political ecologies, power, and social relations (Krieger et al. 2012).

The CSDH adopted a conceptual framework in which a toxic combination of poor social policies and programmes, unfair economic arrangements, and bad politics creates a socioeconomic and political context. These structural factors shape intermediary determinants including the social position of individuals and groups (as indicated by education, occupation, income, gender, or race/ethnicity). This social position then determines the material circumstances of people, their behaviours, social cohesion, psychosocial and biological factors, and their use of the healthcare system. It is this cascade of factors that shapes the distribution of health and well-being (see Chapter 2.1).

For those concerned with improving health and reducing health inequalities, the CSDH provides a comprehensive framework for planning interventions, which although not specific to any particular set of diseases, is directly applicable to oral health (Kwan and Petersen 2010; Marmot and Bell 2011). The commission recommended three principles of action:

To tackle the inequitable distribution of power, money, and resources and create a more equitable socioeconomic and political context.
To improve daily living conditions so that the material circumstances, social cohesion, psychosocial and behavioural factors, and use of health services are more equitably distributed.
To understand the problem and assess the impact of action.

These three activities are neither discrete nor mutually exclusive. For example, action on the distribution of power and resources will improve living conditions and work at either level will involve the same actors to a greater or lesser degree. The emphasis should be to work across all levels of the model (CSDH 2008; Kwan and Petersen 2010) and hence, at all levels of society.

Systematic reviews indicate that downstream, behaviourally based interventions do not appear to reduce inequalities and may increase them (Lorenc et al. 2013). In oral health, it has long been recognized that health education carries its own dangers of disempowerment and victim-blaming. It may increase inequalities in oral health by being more effective among higher than lower socioeconomic groups (Qadri et al. 2018). Conversely, upstream approaches such as structural workplace interventions and pricing policies have the potential to reduce inequalities (Satur et al. 2010). Conway and colleagues' (2008) systematic review associated oral cancer risk with low socioeconomic status but provided evidence to steer health policies which focus on lifestyles factors towards an integrated approach to tackle the root causes of disadvantage.

One refinement of the CSDH approach is the adoption of the principle of proportionate universalism. Marmot (2010) suggested that the gradient of health inequality should be reduced by working to improve the health of all portions of society, but the scale and intensity of the action should be in proportion to the level of disadvantage, for example, by targeting particular interventions at groups at greatest risk within a whole population strategy.

To public health practitioners concerned about social injustice, the growing attention given to health inequalities is exciting. However, the likelihood of reaching a consensus and prevailing upon the power imbalances that structure the social determinants of health and consequent health inequalities has been reduced during the current global economic crisis. Moreover, inequalities appear to be increasing (Thomson et al. 2004). Health inequalities may persist because the increased social mobility of recent generations has left the lower socioeconomic groups more homogeneous in terms of the individual characteristics that predispose to ill health and the difference in the consumption behaviour between socioeconomic groups due to difference in material and immaterial resources such as cultural capital (Mackenbach 2012).

Actions to improve health and reduce health inequality will have similar effects on oral health but some aspects are especially relevant (Box 8.8.1). Therefore, the CSDH framework and these principles will be used in the remainder of this section.

Box 8.8.1 Improving oral health and reducing inequalities within the Commission on Social Determinants of Health framework

1. Tackling the inequitable distribution of power, money, and resources: changing the structural drivers of conditions of daily life
    - Action on health and health equity at the highest level of government with coherent policies across all departments.
    - Redistributive direct taxation systems.
    - Publicly funded action on child development, education, working and living conditions, and healthcare.
    - Market responsibility.
    - Regulation of goods and services with a direct role in health.
    - Political empowerment and fair representation of all.
    - Oral health impact and oral health equity audit of all policies.
2. Improving daily living conditions: changing the circumstances in which people are born, grow, live, work, and age
    - Comprehensive approaches to early life, child survival, and early life interventions.
    - Comprehensive universal social protection.
    - Urban planning and fairness between areas to prevent rural poverty.
    - Full and fair employment with acceptable, safe work, and a healthy work–life balance.
    - Access to universal healthcare.
    - Increasing the availability of fluoride:
        - Water
        - Milk
        - Salt
        - Tablets/drops
        - Toothpastes
        - Mouth rinses
        - Varnishes.
    - Dietary sugars.
    - Oral cleaning.
    - Smoking cessation.
    - Prevention and management of trauma.
    - Use of oral health services.
3. Measuring and understanding the problem and assessing the impact of action
    - Routine systems with relevant measures of oral health, its determinants, and health equity.
    - Dentists and dental public health specialists as advocates.

Tackle the inequitable distribution of power, money, and resources

This part of the CSDH (2008) report makes recommendations which are the most upstream and radical, to change the way that society is organized. Action on health and health equity is advocated at the highest level of

government to ensure effective and coherent policies across all departments. To ensure adequate financing for publicly funded action, the CSDH proposed redistributive direct taxation systems, which demonstrably reduce poverty.

The provision of basic human and social needs including clean water, healthcare, and education are seen as a primary role of the state rather than the market. The commission also proposed that health equity be made a global development goal and that the social determinants of health be placed as a guiding principle across the WHO.

Oral health can be fitted into these broad actions on health inequalities and into all health policies. For example, in many countries dental caries is now a disease of poverty and particularly of children, where redistributive taxation might reduce oral health inequalities. Work with the agricultural sector, especially in relation to the production of cash crops like sugar and tobacco, has obvious applicability to oral health. Further regulation of the imports and marketing of tobacco, alcohol, and cariogenic foods although the evidence base for the effectiveness of the use of such policies is weak.

Oral diseases may contribute to social stratification as they are often visible. The appearance of the mouth is used by others to form social judgements which may limit life opportunities and employment. Seen this way, oral health is not only a goal but a means towards greater equality. However, to reduce the social impact of oral disease, oral health services need to be organized to meet the needs of the population. Where possible there should be universal access to primary oral healthcare services.

Improve daily living conditions

The CSDH recognized that the factors that enable good health are not distributed equally throughout life and made a series of recommendations to improve daily living conditions.

The accumulation of adversity during the life course means there must be comprehensive approaches to early life for child survival and development and comprehensive social mechanisms to support an income sufficient for healthy living. Secure, and fairly paid employment and access to universal healthcare are vital. These actions will have direct and indirect effects on oral health. One well-evaluated strategy for improving daily living conditions is increasing the availability of fluoride. Other strategies focus on

oral health behaviours such as oral cleaning, smoking cessation, and trauma prevention.

Increasing the availability of fluoride

Fluoride prevents or reverses dental caries mainly through topical effects, including the inhibition of demineralization of the tooth structure, enhancement of remineralization with a stronger crystal structure, and inhibition of bacterial enzymes. Consequently, fluoride has been used to prevent caries by adding it to water supplies, toothpastes, foods, drinks, and in professionally applied products.

Water fluoridation

Beneficial effects of fluoride on dental health were inadvertently discovered during investigations of developmental staining of children's teeth in Colorado, United States, due to chronic ingestion of fluoride during tooth development.

Water fluoridation has been designated one of the ten most important public health measures currently available (Centers for Disease Control and Prevention 2010). Dean originally suggested that the optimal concentration for water fluoridation was 1 part per million (ppm) (1 mg/L) (Dean et al. 1950). Recently, the US Department of Health and Human Services (US HHS) suggested 0.7 mg fluoride per litre as the optimum concentration (Spencer and Do. 2016)

The effectiveness and safety of water fluoridation in caries prevention is consistently supported in authoritative narrative and systematic reviews. A systematic review found that water fluoridation was associated with an increase in percentage of caries free children of 15% in deciduous dentition and 14% in permanent dentition, with a 35% reduction in dmft and 26% reduction in DMFT (Iheozor-Ejiofor et al.2015). A national study in Australia found significant association between lifetime exposure to fluoridated water and childhood caries while adjusting for socioeconomic status (Spencer et al. 2018). Water fluoridation was also found to have an effect over and above that of other sources of fluoride, particularly toothpaste.

A direct dose–response relationship was found between water fluoridation and dental fluorosis. At 1 ppm F, the prevalence of fluorosis was estimated

to be 48% and for fluorosis of aesthetic concern 12.5%. Other possible negative effects considered included bone fracture, cancer, Down's syndrome, senile dementia, and goitre. No clear evidence of these potential effects was found.

The cost-effectiveness of water fluoridation depends on the baseline level of caries and the capital costs of the necessary equipment. Fluoridation is most cost-effective in areas where water is supplied to large numbers of people via a single source. Further high-quality research into the safety, efficacy, cost-effectiveness, and impact of fluoridation on quality of life has been recommended.

The introduction of water fluoridation schemes is invariably opposed by active antifluoridationist lobbies. The main arguments against water fluoridation include the safety concerns outlined earlier and ethical objections related to the four principles; respect for autonomy, beneficence, non-maleficence, and justice (Jones and Lennon 1997).

With regard to the claims of loss of autonomy, those proposing fluoridation suggest some reduction of individual freedom of choice is accepted for the overall good of the community. On the argument that only dentate members of society will potentially benefit from water fluoridation, those in favour acknowledge this but argue that fluoridation will 'do no harm' to any members of society. On the principle of justice, some claim that imposing water fluoridation is not fair on those against it. Proponents counter this argument by suggesting that the reduction in inequalities in dental health that fluoridation potentially provides is a just way of helping those least able to help themselves.

A more recent alternative view sees water fluoridation as modestly effective in developed countries with low caries prevalence (as demonstrated by the relatively high number needed to be treated to prevent a case), yet the political battle for new fluoridation schemes may make it very expensive to introduce.

Other vehicles for administering fluoride include the following:

Fluoride milk

Fluoride has been added to milk as an alternative to water since the 1950s in many countries. These schemes vary in the age at which children start drinking the milk, the number of years over which it is administered, the number of days a year the milk is consumed, and the concentration of fluoride added (Marino et al. 2006). There is low quality evidence for effectiveness of fluoridated milk (Yeung et al. 2015).

Salt fluoridation

Fluoridated salt was first used in Switzerland in the 1950s. In certain cantons and in some Latin America countries, all salt for human consumption is fluoridated. Other European countries including France only sell fluoridated salt for domestic use. The typical concentration is 250 ppm F. Several cross-sectional studies report fluoride salt to be effective in reducing caries. However, the reduction of salt consumption is also a public health goal.

Fluoride tablets/drops

Fluoride tablets/drops use also began in the 1950s. They have been used as dietary supplements with different countries having different dosing regimens (based on the child's age, weight, caries-risk, and fluoride in the water). Fluoride supplements resulted in 24% reduction in DMFS compared with no fluoride supplements while the effect on deciduous teeth less clear (Marinho 2014). There is some evidence that when sucked to maximize the topical dose, a preventive effect is observed in deciduous teeth. Two key problems with fluoride supplementation are adherence to dosing regimens and the risk of fluorosis. These concerns have led to a reduction in the use of tablets/drops as a public health measure.

Topically applied fluoride

There are several delivery systems where fluoride is applied to tooth surfaces at high concentrations for a local protective effect.

a) Fluoride toothpaste:

Toothpaste is the most widespread source of fluoride and the decline in caries experience in children in some countries has been attributed to its regular use. The fluoride compounds and concentrations found in toothpastes vary between brands and between countries. The usual concentration is 1,000–1,500 ppm F with higher (over 2,000 ppm F) formulations available. They present an excellent vehicle for the frequent low-dose application of fluoride and their effectiveness in reducing caries in children has been confirmed with a prevented fraction (PF) of 23% with additional prevented fraction if other type of topical fluoride treatment is used (pooled prevented fraction of 10%) (Marinho 2014). The risk of fluorosis from toothpaste can be minimized by using a smear of paste and supervising children under 6 years of age.

Fluoride toothpaste has a distinct disadvantage over water fluoridation as a broad preventive strategy as it relies on people brushing their teeth. In developed countries infrequent brushing and high caries incidence are associated and so the people who have most to benefit from the use of fluoride toothpastes are less likely to use them frequently. In developing countries, there may not be a tradition of tooth cleaning with toothpastes and Western proprietary brands are likely to be expensive. However, cheap locally made pastes can be profoundly effective.

b) Fluoride mouth rinses:

Fluoride mouth rinses have been used extensively for the past 40 years. School-based programmes were common in certain countries although individual home use now predominates. With the general decline in dental caries and the spread of fluoride toothpastes, population-based rinsing programmes are now recommended only for high risk children. Mouth rinsing is not recommended for children under 6 years of age, due to the risk of fluoride ingestion. The two main concentrations available are 0.05% (230 ppm F) sodium fluoride used daily and 0.2% (900 ppm F) sodium fluoride used weekly.

c) Fluoride varnishes/gels:

Topically applied fluoride varnishes and gels have been used widely for over two decades, both as part of community-based programmes and on an individual basis. Fluoride varnishes are professionally applied, with the two most commonly used varnishes containing 22,600 ppm F or 7,000 ppm F (Marinho et al. 2015). Fluoride gels can be professionally or self-applied under supervision. The most commonly used gel is a professionally applied 12,300 ppm F acidulated phosphate fluoride. Due to the risk of excessive ingestion, this gel is not recommended for young children.

A series of systematic reviews of trials have investigated the effectiveness of various topical fluorides expressed as the preventive fraction (the difference in caries increments between the intervention and control groups) (Table 8.8.1).

Table 8.8.1 Relative effectiveness of sources of topical fluoride

Source	ppm F	Prevented fraction (%)
Toothpaste	1,000–1,250	23
	2,400–2,800	36
	1,450–1,500	30
Mouthrinse	230–900	26
Varnish	7000–22,000	43(permanent) 37 (deciduous)
Gel	12,300	28 (permanent) 20 (primary)

Data from Marinho, V. C. 2014. Cochrane fluoride reviews: an overview of the evidence on caries prevention with fluoride treatments. *Faculty Dental Journal*, 5(2), 78–83 and Marinho, V. C., et al. 2015. Fluoride gels for preventing dental caries in children and adolescents. The Cochrane Library.

Dietary sugars

Dietary sugars are a necessary cause of clinically relevant dental decay. Unfortunately, repeated systematic reviews indicate that dietary advice neither reduces their intake nor the incidence of caries (Kay and Locker 1997). Health education programmes only appear to be effective if they also involve the recommendation or prescription of fluoride vehicles.

However, the data suggest that restriction of dietary sugars by other means is preventive. For example, per capita sugar supplies and caries experience data correlate significantly in national ecological comparisons. A children's home in Australia had a dietary regimen with almost no sugar and the children had very low caries levels until they were allowed to make their own food choices at the age of 12. Likewise, caries levels fell in parallel with the decreased consumption of sugars during the Second World War.

It is difficult for people to restrict their consumption of sugars. There are evolutionary reasons for sweet foods and drinks to be pleasant. Consequently 'hidden' sugars are used to make processed foods nicer. In addition, products used to sweeten foods may not be labelled as such, even if they carry similar risks of harm (e.g. fructose corn syrup). To add to this confusion, ecological and animal studies indicate that sugars in whole fruit (sometimes called intrinsic sugars) do not cause caries. Furthermore,

intrinsic sugars have a relatively low glycaemic index and are accompanied by fibre, and so are not usually associated with obesity.

The WHO recommend a daily intake of sugars of less than 5% of the daily energy (Moynihan et al. 2018). In addition, the frequency of consumption of foods containing free sugars should be limited to a maximum of four times per day. A health-directed food policy focusing on the supply of products containing unhealthy sugars is likely to impact on dental diseases as well as broader health problems, given the evidence implicating them as a cause of obesity, myocardial infarction, dyslipidaemia, pancreatitis, and hepatic dysfunction (Lustig et al. 2012).

Such policies should form part of a broader strategy to reduce dietary intakes of refined grain products and potatoes. Possible strategies fall within the framework of education, substitution, regulation, pricing, or provision. Multilevelled fiscal policies can be used to discourage the manufacture and sale of sugar-containing products, including taxing sugar-containing foods and drinks and restricting advertising to children. Beyond approaches aimed at individuals, education can take the form of authoritative dietary guidelines to inform national policies, community initiatives, and caterers. Recommendations by the Finnish National Board of Education reduced the sale of sweet products in Finnish Schools (Kankaanpää et al. 2012). Healthcare workers can routinely ask their patients about sugar consumption (dentists do this all the time!). All of these approaches and direct consumer pressure can help convince caterers and retail outlets to provide food in a way that makes the healthy choices the easier choices.

Dietary sugars can be substituted with artificial sweeteners to reduce caries incidence. Sales of sugar-free carbonated drinks in Europe and North America demonstrate the compatibility of this measure with commercial interests. However, substitution of dietary sugars has only limited potential because the manufacture of many foodstuffs relies on other specific properties of sugars. In addition, some sweeteners have side effects and resistance to the extended use of artificial sweeteners persists.

Oral cleaning

As plaque is a necessary cause of periodontal diseases it seems logical that tooth cleaning (principally by toothbrushing) should be the cornerstone of their management and prevention. Interventions aimed at improving oral hygiene can achieve a commensurate reduction in gingival inflammation.

However, most studies have had short follow-up periods and the effectiveness of even the best interventions diminishes with time. Therefore, few data show that attempts to improve oral hygiene to prevent destructive disease are effective. Nonetheless, the consensus is that the public health approaches to improve periodontal health should include improved oral hygiene.

The relationship between plaque removal and tooth decay is much more contentious. In a carefully designed trial, professional oral cleaning did not demonstrate any additional preventive effect above a standard preventive programme of fissure sealants and locally applied topical fluoride. Reviews of the effect of research methods on the observed relationship between oral cleaning and dental caries concluded that there was ‘no unequivocal evidence that good oral cleanliness reduces caries experience’. This area of research is fraught with difficulty, as apart from the difficulties of measuring dental disease, studies are susceptible to selection bias, leakage of intervention, and the likely confounding effects between self-reported behaviours, diet, and oral hygiene. Studies where professional cleaning has been effective have used toothpastes containing fluoride. What is known is that brushing with fluoride toothpaste is effective in preventing caries. Therefore, brushing as it is currently practised in most developed countries combats both caries and periodontal diseases and is to be encouraged.

It is difficult to achieve sustainable changes in oral hygiene behaviour. Toothbrushing is a habit learned as a young child and is difficult to change later in life, hence interventions via healthcare workers and social agencies working with young children and their parents may be useful.

Toothbrushing often clusters with other health behaviours such as avoiding tobacco use, exercise, healthy eating, and other aspects of hygiene such as hand washing. In turn, these behaviours may relate to personal factors including greater self-efficacy, self-esteem, having confidence in one’s family, life satisfaction, managing in school, and not having other health problems. Unsurprisingly then, toothbrushing is determined by structural and resource-related factors and living conditions. These factors include family structure, social support, external barriers, domestic arrangements, social norms, cultural factors, socioeconomic status, and socioeconomic development. Therefore, actions across all these levels are most likely to improve periodontal health and periodontal health equity.

Smoking cessation

Cessation of smoking decreases the associated elevated risk of oral cancer within 5–10 years. Numerous other oral conditions are directly or indirectly associated with tobacco smoking. Many of these, such as stained teeth, receding gums, and altered taste are readily perceptible to the individual and may encourage or reinforce the desire to stop smoking. The dental team are also often aware of the personal and social circumstances (e.g. pregnancy or a new job) that prompt people to give up. The dental team can hence support smoking cessation by providing advice and signposting dedicated cessation services. Social inequality is evident in smoking rates and is effectively reduced through taxation polices and well-designed mass media campaigns (Purcell et al. 2015).

Prevention of trauma

Maxillofacial trauma is related to environmental and structural factors such as socioeconomic status, alcohol use, and road planning and use. In children, dental trauma is closely related to area-based measures of socioeconomic status and overcrowding. Many of these factors can be alleviated by improving living conditions.

Local and individual strategies can also help reduce trauma to the face and teeth. Playground surfaces can be made of impact-absorbing materials that cushion against trauma. The use of mouthguards is compulsory for some sports in some countries. Mouthguards not only prevent dental injuries, but also prevent laceration of the facial soft tissues against the teeth, reduce the risk of mandibular fracture, and may protect the cranial cavity. The most basic type may be obtained prefabricated in a range of sizes. A more sophisticated type may be adapted to fit the mouth, typically by softening it in hot water first. Custom-made devices are the most comfortable and can be made to support the lower teeth and mandible during trauma

The need for urgent care (particularly teeth that have been knocked out) means that skilled emergency dental services should ideally be available around the clock. Informing athletes and their teachers and trainers of the need for immediate action can reduce the impact of the trauma. Unfortunately, orthodontic treatment of protruding front teeth is complex and prolonged, but can be justified in children of 8 or 9 years to reduce the risk of trauma

Use of health services

Internationally, the emphasis and resources within dentistry remain focused on downstream approaches to ‘cure’ patients of their dental diseases, rather than evidence-based strategies to improve the oral health of populations (Baelum 2011).

Similar problems exist with medical, and dental care. Resources are constrained and may be poorly allocated. Services still cluster around people who can afford them, while those who cannot, have little control over their own health and healthcare. In every country of the world, there are people who cannot attend and/or afford dental treatment and even in well-developed socialized systems of dental care major inequalities exist.

Specific changes to ensure access to dental services can be categorized in the framework used by Penchansky and Thomas (1981). Services must be available, accessible, affordable, acceptable, and accommodating. This framework is broadly compatible with the characteristics of dental services as seen within Andersen’s (1995) behavioural model of access.

Increasing availability has a direct effect on service use. A number of countries including Australia, New Zealand, Canada, and the United Kingdom employ DCPs with a limited repertoire of treatment options (variously called school dental nurses, dental auxiliaries, and dental therapists). The scope of practice of dental therapists varies from country to country. In general, they may undertake diagnostic procedures, treatment planning, and preventive services, place fillings in primary and permanent teeth, and extract primary teeth. They may also be permitted to extract permanent teeth. Therapists can be used to increase access to care by supplementing the volume and reach of services, which enhances equity (Dyer et al. 2013). Therapists are socially acceptable where they are integrated into existing dental systems. Available data suggest that therapists offer care that is similarly effective to that provided by dentists. In developing countries with a growing incidence of dental caries which may not be able to afford sufficient dentists, dental professionals may be an appropriate solution.

One particular aspect of dentistry in many countries that could be revised is the direct fee-for-service system of payment to dentists. Fee-per-item service payments encourage dentists to work quickly and may incentivize overtreatment rather than prevention unless there is a specific fee for this. On the other hand, services based on capitation per patient enrolled reduce

restorative treatment and increase preventive care with no evidence of 'supervised neglect'.

The acceptability of dental services was highlighted in a qualitative study of people who did not go to the dentist. As well as being influenced by the perceived accessibility of care, participants were swayed by their trust in dentistry and their perceptions of oral health as a commodity. For these people at least, greater marketing may have been counterproductive in encouraging use of dental services.

Dental services in middle and low-income countries

Non-industrialized countries usually suffer from resource constraints including workforce, appropriate technology, and reliable power supplies. For example, the dentist: population ratio in many countries in Africa is around 1:150,000 compared to 1:2,000 in most industrialized countries. The ratio recommended by the WHO is 1:7500 (Kandelman et al. 2012). Access inequalities are exacerbated by the unequal distribution of dentists and their migration from middle and low-income countries to more developed countries.

The limitations of the traditional curative approach to dental health are more extreme in the context of the developing world. The surgical approach to dentistry is technology intensive and requires the availability of continuous power and expensive equipment. Dentists, therefore, need to treat patients who can help them recoup their costs. These pressures limit the availability of services and contribute to the inequalities in their provision. Large parts of the Western model of dental care may be inappropriate in developing countries, including an overemphasis of clinical surveys in healthcare planning. Services based on normative assessment limit community participation in healthcare and ignore the sociodental implications of oral disease. In one notorious example, survey data used to calculate the periodontal treatment needs of children in Kenya would have used the entire national dental workforce for up to 21 years. Services could concentrate on the relatively few conditions that comprise the bulk of oral health problems: toothache (not *tooth decay*), trauma, oral infections, and neoplasms.

The primary oral healthcare approach (PHCA) is still relevant in all countries but particularly so in the developing world. It has five principles:

Equitable distribution of services: The 'inverse care law' between the availability of services and the need for them also occurs in dentistry. It is particularly extreme in countries where there are wide disparities between rich and poor. In Africa, 80% of the trained professional personnel live and work in affluent neighbourhoods in cities although the same proportion of the population lives in rural areas. The scope for other DCPs in developing countries may be greater since political lobbies of dentists may be less well established than in industrialized nations. DCPs can provide simple, but essential treatments to extend the availability of services and reduce inequalities in access.

Community involvement in health: this means that people are allowed to take control of their own health and is necessary if programmes are to thrive. It is perhaps the most difficult aspect of the PHCA since it requires health professionals to relinquish their traditional hierarchical role. Individuals and communities often also regard health as beyond their control and may not consider oral health a priority. There are isolated examples of wide involvement in oral health. In Glasgow, Scotland, community-based Oral Health Action Teams (partnerships of parents, teachers, nursery nurses, health visitors, and dentists) have reduced caries levels in young children in deprived areas of the city (Blair et al. 2004).

Focus on prevention: prevention of oral diseases is universally accepted as an essential component of care, but in the past has involved people as passive recipients of information rather than active participants in health promotion.

Use of appropriate technology: 'appropriate technology' does not connote 'cheap' and 'second rate', but an approach which recognizes the needs and resources of the local community. For example, ART combines these requirements with knowledge of dental caries progression and developments in dental materials science.

Multisectoral approach: we have seen how an effective health strategy might involve a number of departments of both national and local governments, water providers, the educational system, community members, and healthcare workers. All of this needs to be integrated coherently to go beyond just using the resources of other sectors to promote oral health.

Measure and understand the problem, and assess the impact of action

The third aspect of the CSDH framework would involve monitoring the social determinants of oral health. This requires routine systems to record relevant measures of health, its determinants, and health equity. Such data can be collected during dental treatment or through surveys.

New evidence on the role of social determinants in oral health equity and evaluations of interventions to reduce inequality should emerge from the international emphasis given to the topic. For example, WHO attention on the social determinants of health should make funding for such work a priority. One area where the global oral health inequalities research agenda can make an immediate impact is to provide a forum for sharing and interpreting new evidence.

Training on this topic is available through undergraduate and postgraduate courses for dentistry, although their extent and focus varies. The WHO Oral Health Programme provides guidance on tackling oral health inequalities but could benefit from greater resources (Kwan and Petersen 2010).

Future developments

Several trends in oral health have been observed. First, some countries, particularly developing ones, may experience increases in dental caries due to the adoption of diets high in sugars. These trends are worrying even if they are limited to more affluent city dwellers as the increase in treatment and the burden on developing economies while this burden will be moderated by the low levels of perceived need in communities unused to receiving dental treatment.

Second, the fall in caries prevalence seen in developed countries over the past 40 years appears to have slowed, with evidence of wide inequalities in dental caries and its impact on people’s daily lives. Third, in many developed countries the combination of demographic changes, changed attitudes towards oral health, and the preservation of teeth produces an interesting pattern. The growing number of older people who will live longer and retain many heavily restored teeth will increase the need for more care, some of it more complex, which in turn will drive more specialization.

The deprofessionalization of dentistry continues to gather pace and is manifest in several different forms. In many developed countries patients are

demanding ‘rights’ as consumers of care, even as marketing theory is being applied to dentistry, which places consumer satisfaction as being essential for business success. Similar principles are cornerstones of the new public health. Health promotion takes public involvement in oral health well beyond clinical dentistry. Even within clinical care, satisfaction is an integral part of the process of care rather than just an outcome. Other agencies, such as governments and insurance companies, are increasingly involved in healthcare. Externally applied measures to minimize the costs of care and increase the accountability of healthcare organizations while assuring the quality of care all serve to reduce professional power within dentistry.

Gigerenzer and Gray (2011) have named the twenty-first century as the *century of the patient*. They suggest widespread stakeholder participation to solve common healthcare problems using all the theoretical and practical knowledge available.

This trend of deprofessionalization is likely to continue and may help to make oral care more relevant to the needs of the people it serves. Deprofessionalization and greater lay involvement in dentistry, both at the individual and community level, will reduce the power structures and hierarchies that underpin the social determinants of health. This might be particularly important where perceived social position is a cause of health inequality independent of objective assessments of socioeconomic status. Given that professions are likely to resist any tendency to undermine their power, there is an opportunity for dental public health to facilitate and manage the deprofessionalization of dentistry.

Evidence base

Only a minority of practitioners and academics contribute to the growth in the evidence base of dentistry through systematic reviews. Unfortunately, these reviews repeatedly conclude that there is a dearth of good primary data on which decisions can be based. While a greater evidence base for individual care is needed, more research is also needed on the benefits of interventions at a population level, not only to improve health, but also to reduce inequalities.

Other chapters in this text will consider the evaluation of health promotion in some detail (see Chapter 2.1), but the debate about controlled trials in public health continues. Health promotion takes place in the ‘real world’ and

other factors and time intervene between the intervention, and health outcomes. For example, implementing a life course approach to reduce inequalities may take decades before its benefits are manifest. These factors have led the WHO (1998) to conclude that 'The use of RCTs to evaluate health promotion initiatives is, in most cases, inappropriate, misleading, and unnecessarily expensive'. Even the keenest advocates of RCTs acknowledge that they are unsuitable for evaluating legislative and policy changes. However, many of the problems often cited against conducting trials in public health can be overcome.

A further problem in both clinical and industry-sponsored trials is the widespread failure to identify treatment effects. Further consideration of methodology may be required ahead of new evaluative research.

Technology

Technological developments also influence oral health and care. In developed countries, osseointegrated implants are increasingly used to support dental prostheses. At present, however, implant treatment demands specialist expertise, requires regular maintenance, and is therefore costly. Implants treatment is hence limited to those who can afford it and thus contributes to inequalities in oral health. Other more long-term technological possibilities include a vaccine for dental caries, growing teeth from stem cells, the use of nanotechnology and laser drills.

Advances in 3D imaging and printing have the potential to simplify and streamline the production of prostheses such as crowns and dentures. However, even as these technologies are introduced, it remains to be seen if they will have public health benefits.

Cosmetic dentistry

Cosmetic dentistry procedures include bleaching teeth and the use of veneers to change their appearance.

Cosmetic dentistry can be seen as the medicalization of beauty and as a form of iatrogenesis. Supplier-induced demand is evident when dentists draw patients' attention to minor dental anomalies (that may have no effect on their lives) and suggest they have them corrected. Attractiveness is

perhaps more important now than ever before and society is said to be suffering from a normative discontent with personal appearance. Dentistry may contribute to these problems if the availability of treatment to enhance dental appearance makes deviations from the norm less acceptable. This message is amplified in printed and broadcast media that expose us to enhanced images. Photographs in magazines have whiter and straighter teeth than would normally be encountered and exposure to these images increases our dissatisfaction with our own appearance. In addition, cosmetic dentistry will only be available to those who can afford it. It may be that the visible consumption of cosmetic dentistry will further distinguish socioeconomic groups and so contribute to the stratification of society and social inequalities. From this perspective, cosmetic dentistry might have adverse effects both on the people who receive it and on wider society. Consideration may be required about whether its growth should continue unchecked.

Consumerism and the role of industry in oral health

Consumerism is widely criticized from the perspective of overconsumption, its links with media culture, and from socialist and feminist perspectives. Its role in oral health is not so clear cut. The addition of fluoride to toothpastes has been one of the most successful dental public health interventions of all time. Moreover, its effect is cumulative and is staggering when seen over decades. The first fluoride toothpastes were introduced in the 1950s but sales rose dramatically in the United Kingdom during the 1970s (the proportion of toothpaste sales containing fluoride rose from less than 10% in 1970 to more than 90% in 1976).

Although dentists were involved in the development, evaluation, and promotion of fluoridated toothpastes, it was the commercial interests of home-care product manufacturers that drove this development. There are also numerous examples of manufacturers and dental organizations working together to promote oral health that continue to this day.

The commercial marketing of dental care products has other advantages. It has raised the prominence of oral health and reinforces the idea of frequent oral cleaning as a social norm. In addition, the positive ways in which oral healthcare products are advertised has made a healthy mouth seem attainable.

Conclusions

In summary, we have argued that poor oral health is a major public health problem with a huge population burden of oral disease because of the large numbers of people affected. While the incidence of dental caries has fallen in the developed world, the prevalence of the condition would be staggering when compared to any other disease. Periodontal diseases, cancer, and trauma all pose specific problems. All these diseases have significant impacts and create a considerable burden to both individuals and the community. The links between oral and general health indicate that strategies to improve both sets of problems and reduce inequalities should be integrated within the framework advocated by the CSDH. Several factors, including tighter financial pressures, trends in oral health, the deprofessionalization of dentistry, the role of consumerism in oral health, and the need for a better evidence base will modify this endeavour, as will the growth of skill mix, technology, and cosmetic dentistry.

Musculoskeletal disorders

Lope H. Barrero and Alberto J. Caban-Martinez

Introduction

What will be included in this chapter?

Musculoskeletal disorders (MSDs) refer to a large variety of health conditions that affect muscles, tendons, ligaments, nerves, and bones. Conditions such as osteoarthritis, osteoporosis, low back pain, rheumatoid arthritis, and carpal tunnel syndrome fall into this large category of health conditions.

Multiple factors related to the intrinsic characteristics of individuals, their environment, and their daily activities can contribute to the occurrence and burden of MSDs. The relative contribution of these factors can vary across populations in different parts of the world. As we learn more about the mechanisms through which these conditions occur, we have been able to improve our understanding of how multiple complex pathways can take a person from a healthy status to a disease state. This new knowledge about the diagnosis and pathogenesis of MSDs has emphasized the fact that in reality, MSDs can include several very different conditions, which in essence implies that no single pathway for diagnosis, treatment, or rehabilitation can be effective, not even in very well defined specific populations.

The importance and major public health burden of MSDs is rooted in the fact that these conditions occur more frequently than many other conditions that can affect human health; and when they do occur, they tend to last longer than other conditions, coexist with other, sometimes deadly conditions that are caused by the same factors or that are complications resulting from them. For example, in the United States, approximately 50 million adults have a doctor diagnose of arthritis, yet 1.2 million, or nearly one in four adults with arthritis (24%), also have heart disease (Cisternas et al. 2009). These characteristics translate directly into a large burden to society that can appear in the form of direct health services costs, reduction in opportunities for those affected and suffering for those affected and their families. Furthermore, because of the differences in access to healthcare, the burden of these conditions may vary substantially between different latitudes, generating questions about equality and social justice.

In this chapter we first present a brief description of some of the most important MSDs of public health importance. We then briefly describe what we know about their causes and what is already known about how to prevent them or reduce their impact to society. We will also describe the scope of the problem from a public health perspective. We also present a brief account on the epidemiology of these conditions; the estimated costs to society; the most important barriers that prevent persons from obtaining some relief. Lastly, we summarize recommendations for public health policy action and for future research.

MSDs definition and classification

There are a broad scope of health conditions that comprise MSDs including inflammatory conditions such as gout and rheumatoid arthritis, age-related diseases such as osteoarthritis and osteoporosis, conditions with ambiguous aetiologies such as fibromyalgia and low back pain, conditions due to injuries from occupational exposures, sports injuries, as well as injuries resulting from slips, trips, and falls. While some of these conditions present with acute onset and short duration, a larger proportion of these disorders reoccur or become lifelong health conditions (Woolf et al. 2010). These conditions can substantially impair both mental (Carder et al. 2013; Holmgren et al. 2013) and physical function and therefore are a major determinant of the health of the world population.

Different classifications of MSDs can be found in the scientific literature based, for example, on body part affected, whether it has a systemic origin or based on the external causal factor (e.g. whether it is work-related or not).

The International Classification of Disease (ch. XIII) provides a useful framework with which to classify groups of diagnosis of MSDs (ICD-10) (http://apps.who.int/classifications/icd10/browse/2010/en#/XIII) and they include:

Arthropathies: Disorders affecting predominantly limb joints including those due to microbiological agents (e.g. rheumatoid arthritis, juvenile arthritis, gout, psoriatic spondylitis).
Systemic connective tissue disorders: Including autoimmune disease and collagen (vascular) disease (e.g. systemic lupus erythematous and Sicca syndrome (Sjören)).
Dorsopathies: Disorders of the spine including deforming dorsophathies, spondylopathies and other dorsopathies (e.g. cervicalgia, sciatica, and low back pain).
Soft tissue disorders: Disorders of muscles (e.g. muscle strain).
Osteopathies and chondropathies: Including disorders of bone density and structure (e.g. osteoporosis); and chondropathies (e.g. juvenile osteochondrosis).
Other disorders: Including conditions nowhere else classified including post-procedural musculoskeletal disorders and biomechanical lesions not elsewhere specified.
Additional MSDs may be found among other groups of diagnosis: MSDs involving nerve damage (e.g. carpal tunnel syndrome) can be found among diseases of the nervous system. Also, MSDs involving sprains and strains for joints and ligaments can be found in the injury category.

Major MSDs: case definitions, natural history, pathophysiology, risk factors, and treatment

While there are many types of MSDs, musculoskeletal tissue degeneration in general, can be initiated by systemic disease, trauma, and repeated biomechanical strain—all of which can lead to disability and pain. For example, autoimmune diseases can initiate and sustain damaging processes to body tissues including musculoskeletal tissue (Smolen and Aletaha 2008). Similarly, hormonal imbalances can generate loss of structure in bones and result in osteoporosis. On the other hand, trauma resulting, for example from a fall at an early age, can initiate abnormal processes of gene expression or result in incomplete repair processes that end up affecting musculoskeletal tissue structures. Also, repeated loads can result in tissue microtrauma that affects its function and eventually accumulates to major damage if recovery is not allowed.

Environmental factors (e.g. eating and physical activity habits) and individual characteristics (e.g. genetic factors and age) are determinants of MSDs (Gabriel and Michaud 2009) influencing the initiation and development of the disease process through complex relations. For example, poor eating habits can result in overweight individuals, which can affect the biomechanical loading on joints and hence lead to osteoarthritis conditions (Guilak 2011; Vincent et al. 2012). Similarly, genetic factors can be involved in the onset of systemic inflammatory disease and can also influence body response at different stages of the disease process. On the other hand, ageing activates several different biochemical processes of tissue degeneration through insufficient expression of tissue components or the occurrence of other age-related diseases with the capability to influence the process of tissue degeneration.

Tissue degeneration is thought to accumulate throughout the life course, although determining the beginning of the disease process is difficult. The accumulated damage can be seen clinically, based on radiographic or serologic evidence. For example, tissue tears and tissue deformation can be seen based on imaging techniques. An important body of research has been developed on new biomarkers to track the onset and development of disease (Naylor and Eastell 2012; Pisetsky et al. 2012; Rousseau and Garnero 2012). Nevertheless, such imaging findings are poor to moderate predictors of disability. For the specific case of the upper extremity, a recent review concluded that there is still limited evidence of an association between quantitative medical imaging biomarkers and neck and shoulder MSDs.

The key feature determining disability and rehabilitation from MSDs among individuals is the presence of pain (Laisné et al. 2012). Once pain occurs as a result of MSDs, most likely it will occur again intermittently throughout the lifetime. If pain lasts enough and/or is perceived as strong enough it will result in disability. How pain is managed is therefore crucial as it ultimately determines the burden of MSDs to individuals, their families, and society. Although the ways in which pain exerts the effect on how persons feel are complex and remains undetermined, it appears that emotional processes (e.g. depression) may be involved in how pain is perceived; and therefore, on how large is the consequence of pain. Cognitive (e.g. increased attention to pain); behavioural (e.g. low levels of physical activity, limitation of adaptive pain coping behaviour, and impairment of social support); and neurophysiological factors (e.g. enhanced CNS pain processing, impaired neuroendocrine function) seem to mediate the pathway from emotional disturbances to final outcomes (Edwards et al. 2011).

Low back pain, neck pain, osteoarthritis, osteoporosis, and rheumatoid arthritis are some of the most common conditions among MSDs causing the largest public health burden to society worldwide. A brief account of the natural history, diagnosis, and treatment of a few major conditions is presented next.

Low back pain

Definition

Low back pain (LBP) is characterized as pain manifesting from the anatomic area between the twelfth rib and the superior aspect of the thigh either with or without radiating leg pain (Krismer and Van Tulder 2007). LBP can result from several different causes. Non-specific LBP has received the most attention from the healthcare arena because it represents more than 80% of the low back pain cases seen in the healthcare setting. These cases of LBP can be initially classified based on whether or not it presents with pain in one or two legs; and based on pain duration.

Pathophysiology

The pathophysiology of LBP can generally be classified as either mechanical or non-mechanical in origin (Biyani and Andersson 2004). Mechanical LBP can be due to disk herniation, where the annulus fibrosis around the disk tears, allowing the disk nucleus to push against nearby nerve roots and cause pain. Another possible mechanical pathway for LBP that is commonly seen in ageing populations are arthritic spurs that impinge about adjacent nerve roots in the spinal canal igniting pain. As we age, bone remodelling can cause spurs to develop at the vertebral bodies and these spurs can directly compress these nerve roots and vascular structures leading to pain, inflammation, and secondary oedema. Non-mechanical LBP can be caused by neoplastic, infectious, inflammatory arthritis or other diseases (e.g. Paget's disease, Scheuermann's disease, Basstrup's disease, etc.) (Jarvik and Deyo 2002).

Natural history

Most people will feel LBP at least once in their lives independently of the root causes; although only a proportion of them are likely to seek healthcare services (Balagué et al. 2012). Among individuals with non-specific LPB, the frequency and duration of pain can vary considerably, with some individuals reporting multiple periods of pain with interspersed period of less severe or no pain. This period of pain could be brief, lasting a few days, or it could be longer, lasting a few weeks or even months that eventually leads to disability. If the pain lasts for a significantly extended period of time beyond the normal healing period of approximately 2 months, then a chronic pain syndrome could arise (Krismer and Van Tulder 2007). Studies have also shown that when pain radiates down one or both legs there is a strong association with more significant loss of function (Hoy et al. 2010a).

While a great majority of adults will experience one episode of back pain during their life, many adults will also experience new episodes of back pain (Jeffries and Grimmer-Somers 2007). In fact, recent studies have classified individuals who seek healthcare for back pain into four categories, including: those persons with 'persistent mild' pain, those who start with mild pain, progressing quickly to 'recovering' with no pain; those with 'severe chronic' pain who have permanently high pain; and those with 'fluctuating' pain whose pain varied between mild and high levels (Dunn et al. 2006).

Risk factors

Risk factors for a new episode of LBP may include: poor general health, female gender, and body weight in women (Croft et al. 1999); genetics and age (incidence is higher in the third decade (Hoy et al. 2010a), occupational exposures and education (Hoy et al. 2010a)). Although by definition non-specific LBP has unknown causes, there are known associations between LBP and degeneration of the lumbar discs seen with clinical imaging. The scientific literature suggests that mechanical factors are associated with self-reported LBP; however, several meta-analyses and systematic reviews have suggested that mechanical factors such as awkward posture, manual material handling, pushing, or pulling, and prolonged occupational sitting are not causal of LBP. Obesity and smoking may also play a role (Balagué et al. 2012). Genetic factors may also be implicated via disc narrowing effects on pain or via two genes (i.e. catechol-O-methyltransferase [COMT] and the μ-opioid receptor [OPRM1])

implicated in pain perception, signalling, psychological processing, and immunity. Interleukin-1 gene cluster polymorphisms are associated with modic changes and might have a pathogenic role. Genotype has also been reported to be associated with the outcome of surgery for degenerative disc disease (Balagué et al. 2012).

Treatment

In general, the recovery from acute LBP either with or without radiating pain down the leg has a favourable recovery profile. While certain interventions such as stress management, shoe inserts, or insoles, back supports, ergonomics or back education, and reduced lifting programmes are not proven to be effective; exercise interventions seem to be the most effective in reducing LBP. For example, intervention studies have shown that when compared to individuals not randomized to the intervention group, those who receive specific training and advice on proper manual material handling either with or without the use of assistive devices, report less sick leave (Balagué et al. 2012).

Neck pain

Definition

Neck pain (NP) encompasses a broad range of different clinical presentations and has been defined as pain in the neck that lasts for at least one day either with or without radiating upper limb pain that is associated with activity limitations (Hoy et al. 2010b). NP can result from different specific causes (e.g. trauma) or serious pathologies (e.g. inflammatory disorder, radiculopathy, or myelopathy); but in the majority of cases, as it is for LBP, NP is non-specific (Hoving et al. 2001).

The Bone and Joint Decade's Task Force on Neck Pain and Its Associated Disorders (Carroll et al. 2008) recommended to classify NP through the following scheme:

Grade I neck pain: No signs or symptoms suggestive of major structural pathology and no or minor interference with activities of daily living; will likely respond to minimal intervention such as reassurance and pain control; does not require intensive investigations or ongoing treatment.
Grade II neck pain: No signs or symptoms of major structural pathology, but major interference with activities of daily living; requires pain relief and early activation/intervention aimed at preventing long-term disability.
Grade III neck pain: No signs or symptoms of major structural pathology, but presence of neurologic signs such as decreased deep tendon reflexes, weakness, and/or sensory deficits; might require investigation and, occasionally more invasive treatments.
Grade IV neck pain: Signs or symptoms of major structural pathology, such as fracture, myelopathy, neoplasm, or systemic disease; this grade requires prompt investigation and treatment.

Pathophysiology

In a large number of individuals, neck pain can be a result of either muscular or ligamentous factors related to posture, poor ergonomics, stress, and/or chronic muscle fatigue. Neck muscle pain can also develop secondarily as a consequence of postural adaptations to a primary source of pain in the shoulder or other upper extremity joints (Bogduk 2011). Individuals with degenerative arthritis in the upper cervical joints can present with severe neck pain that transmits down into the neck or to the back of the ear.

Natural history

Neck pain is first experienced in childhood or adolescence and can manifest several times over the life course. In fact, a large proportion of individuals with neck pain never really experience complete resolution of their pain. Recent research studies have shown that between 50% and 85% of those who experience neck pain at some point in their life, they will report neck pain again 1 to 5 years later (Haldeman et al. 2010). This neck pain experience appears to be similar in the general population, workers and among individuals who experience motor vehicle crashes (Haldeman et al. 2010).

The presentation of neck pain among individuals who seek healthcare can vary and includes concomitant pains such as headache, shoulder, upper limb, upper and/or lower back pain (Leaver et al. 2012). However, among

individuals with non-specific neck pain, the origin of the pain and its progression can also vary. In addition, pain arising from anatomic regions other than the neck can be explained as referred pain from innervated cervical spine structures, or as other regional conditions coexisting with neck pain, or as the presence of a generalized, widespread pain syndrome involving neck pain. Nonetheless, neck pain can be a complex health condition that is difficult to treat and contributes significantly to the burden of MSDs (Leaver et al. 2012).

Several factors can affect the course of neck pain. For example, younger age is associated with a better prognosis, whereas poor health and prior neck pain episodes were associated with a poorer prognosis. Poorer prognosis was also associated with poor psychological health, worrying, and becoming angry or frustrated in response to neck pain. Greater optimism, a coping style that involved self-assurance, and having less need to socialize, were all associated with better prognosis. Specific workplace or physical job demands were not linked with recovery from neck pain (Haldeman et al. 2008).

Risk factors

Poor general health, smoking, higher pain, and lower Short-Form Health Survey (SF-12) mental component scores have been reported to be independently associated with higher level disability resulting from neck pain (Leaver et al. 2012). Several epidemiologic studies suggest that risk factors for neck pain have a multifactorial aetiology, including for example, age, gender, and genetics. However there is no evidence that common degenerative changes in the cervical spine are risk factors for neck pain. Research studies have also documented that modifiable factors for neck pain include smoking, exposure to environmental tobacco, and physical activity participation. Occupational health studies have also documented that high quantitative job demands, low workplace social support, sedentary work position, repetitive work, and precision work have been associated with increased risk of neck pain (Haldeman et al. 2008).

Treatment

Generalized neck pain can be treated conservatively with the use of over-the-counter pain medications, ice, heat, and massage, and strengthening and/or stretching exercises at home. Current strategies suggest that if the pain persists after a few weeks of conservative treatment, then further evaluation is warranted (Haldeman et al. 2010). There is a dearth of high-quality evidence elucidating the best specific treatment for neck pain in general. For instance, there are many reviews as there are controlled trials of therapies for neck pain; yet for many interventions, there is no concordance in the conclusions drawn by reviewers. Few studies have been conducted on the long-term effects of treatments for neck pain. A study conducted by Haldeman et al. (2008), suggested that compared to quality of life years with the use of standard NSAIDs, Cox-2 NSAIDs, exercise, manipulation, and mobilization among adults with neck pain; active treatments are not significantly superior to any other treatment option in the short or long term even after controlling for adverse event risks, treatment effectiveness, and patient-preferences for health outcomes in their models (Linton and van Tulder 2001; Haldeman et al. 2008).

Osteoarthritis

Definition

Osteoarthritis (OA) is a degenerative disorder of the joints that can also be termed degenerative joint disease degenerative arthritis or osteoarthrosis. Together they comprise a group of joint conditions that involve degradation of joint tissues, including the articular cartilage and subchondral bone. Joints of the hip and knee are most frequently affected, but also the joints of the hand, spine, and feet are typically affected. Individuals with these conditions report feeling specific pain, tenderness, stiffness, and locking around the joint. Among persons with chronic joint degeneration one may see muscles shrinkage and ligaments loosening around the joint. Current classification schemes for OA include documentation of loss of cartilage, subchondral sclerosis, subchondral cyst formation, and osteophytes on radiological imaging, and self-reported joint pain (Fransen et al. 2011).

Pathophysiology

OA is said to be primary if originated without a known cause (Punzi et al. 2010). However, OA can also be secondary to other diseases such as congenital joint disorders and diabetes. Traditionally, osteoarthritis was

thought to affect primarily the articular cartilage of synovial joints; however, pathophysiologic changes are also known to occur in the synovial fluid, as well as in the underlying bone structures, the overlying joint capsule, and other joint tissues (Punzi et al. 2010). During the early phases of osteoarthritis, swelling of the cartilage usually occurs, because of the increased production of proteoglycans that reflects an effort by the cartilage's cellular structures to repair cartilage damage. This phase may last for several years or decades and is characterized by intense repair of the articular cartilage. As osteoarthritis progresses further, however, the cartilage eventually begins to soften and lose elasticity and thereby further compromising joint surface integrity. In the long run, this loss of cartilage results in loss of joint space (Punzi et al. 2010).

Natural history

OA is a joint condition that involves a slow, progressive degeneration of the joint and is the most common type of all arthritis conditions. We know that OA develops as a result of articular cartilage damage that can be triggered by a complex interplay of genetic, metabolic, biochemical, and biomechanical factors with secondary involvement of the inflammation pathway. The overall natural process involves interactive degradation and repair processes of cartilage, bone, and synovium. Of all the cells involved in the aetiology and pathogenesis of OA, chondrocytes play a large role. Studies on animals and humans suggest that these cells exhibit numerous metabolic dysfunctions leading to OA. This pathology more than any other disease pathology can result in difficulties in daily activities such as walking, stair climbing, and other lower extremity tasks (Gabriel and Michaud 2009).

Risk factors

OA is said to be a primary disorder if it originates without a known cause; although evidence suggests that risk factors such as genetic predisposition, age, obesity, female sex, greater bone density, joint laxity, and excessive mechanical loading are associated with its aetiology (Punzi et al. 2010) Recent evidence from North American and European cohorts suggest that obesity or heavy occupational physical activity are risk factors for symptomatic knee and hip OA (Gabriel and Michaud 2009; Fransen et al. 2011) In addition, other studies have documented that history of joint injury, frequent stair climbing or frequent lifting of heavy weights are significantly associated with hip OA where the strongest association was among individuals with a history of joint injury. In a case–control study in Japan, there was an association with occupational lifting but no association with obesity (Fransen et al. 2011). In other study, OA has been associated with high obesity levels and cardiovascular disease which can cause synergistic effects (Punzi et al. 2010).

Treatment

While there is no known cure for osteoarthritis, certain treatments can help to reduce pain and maintain joint movement. Treatment generally includes exercise, lifestyle modification (e.g. diet) and pain relievers. If the condition is severe, joint replacement surgery is typically recommended. While specific medications designed to reduce pain (e.g. acetaminophen and opioid analgesics are helpful, they do not have an effect on joint inflammation as do non-steroidal anti-inflammatory drugs). In more severe cases of OA, there are two types on injects that have shown moderate evidence for pain improvement: steroid (i.e. glucocorticoid) injections and injections of a liquid known as hyaluronate designed to mimic the natural fluid found in joint space (Iagnocco and Naredo 2012). Platelet-rich plasma (PRP) is an autologous blood product that contains a high concentration of platelets and has emerged as a viable treatment method for individuals suffering from OA (Bennell et al. 2017). Growing epidemiologic data suggests that PRP for the treatment of OA is efficacious and safe, particularly during early states of OA (Meheux et al. 2016). Once these conservative and minimally invasive approaches have been exhausted, a surgical approach to rehabilitating the osteoarthritis joint may be needed (Iagnocco and Naredo 2012).

Osteoporosis

Definition

Osteoporosis is classified as either primary or secondary depending on what is causing the disease. The primary form of osteoporosis is a metabolic bone disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and increased fracture risk (Riis 1993). Secondary

osteoporosis can result from a variety of the chronic conditions that significantly contribute to bone mineral loss, or it can result from the effects of medications and nutritional deficiencies. The World Health Organization (WHO) defines osteoporosis using bone density such that a bone density score that is 2.5 standard deviations (SDs) or more below the young adult mean value. However, individuals with bone density between scores 1 and 2.5 SDs below average are said to have osteopenia (Kanis et al. 1994). In the case of the spine, decreased bone density imparts increased risk for bone fracture; for every 1 SD decrease in bone density of the spine there is an increased risk for new vertebral fractures by factor of 2.0 to 2.4 (Wasnich 1993).

Pathophysiology

Challenges in bone mass acquisition during human growth and development and accelerated bone loss in the period after peak bone mass are both leading mechanisms for the development of osteoporosis. Studies have shown that both of these mechanisms are influenced by environmental and genetic factors (Iagnocco and Naredo 2012). In postmenopausal women, studies have attributed about two-thirds of the risk of fracture to be related to the premenopausal peak bone mass (Farmer et al. 1984). In twin and mother-daughter dyad studies, about 40–80% of the variability observed in bone mass can be attributed to genetic factors. In fact, biological studies have suggested that genes regulating oestrogen receptors, transforming growth factor-β, and apolipoprotein E and collagen, influence the development of osteoporosis. Conversely, bone loss, is more strongly influenced by individual level factors such as nutritional, behavioural, and pharmacologic factors yet still associated to a lesser degree with oestrogen genetic factors (Ronis et al. 2011).

Natural history

Osteoporosis is a complex and dynamic disease of bone where there is asymptomatic reduction in the quantity of bone mass per unit volume. When the bone mass reaches a very low threshold, the structural integrity and mechanical support provided by the bone fails leading to fractures. The overall natural process of this disease, involves a dysregulation of the homeostatic processes between osteoclastic (bone destruction) and osteoblastic (bone growth) activity. If sufficient remodelling in one direction occurs (i.e. more bone destruction than growth), the bone becomes weakened and could lead to fractures (Hoy et al. 2010b; Hoy et al. 2012).

Risk factors

There are several well-known modifiable and non-modifiable risk factors for osteoporosis. Non-modifiable risk factors include age, body size, race, and family history (Drake et al. 2012; Wright and Saag 2012). Recent epidemiologic studies in the US suggest that men and non-white women at risk add approximately 30 to 54 million affected persons. Racial and ethnic differences in the prevalence of osteoporosis and osteoporotic fractures have been well documented (e.g. Ibrahim et al. 2012). Some studies have also noted that women of Asian descent have lower bone mineral density that white women (ILO 1999). In terms of age, studies have shown that decreased bone mineral density and osteoporotic fracture rates increase throughout the life course. Similarly, men also suffer from osteoporosis yet not at the same rate as women (ILO 2000; Jarvik and Deyo 2002). Modifiable risk factors, on the other hand, include sex hormone deficiencies, diet, certain medical conditions (e.g. anorexia nervosa), and medications, lack of physical activity, heavy alcohol consumption, and smoking (Wright and Saag 2012).

Treatment

The treatment plan for osteoporosis is often multifaceted including pharmacologic and behavioural interventions to reduce risk of fracture and improve bone mineralization. For example, a treatment plan could include activities in exercise, improving nutrition, and educational training on the prevention of falls. Pharmacologic interventions often complement these approaches and include drugs that modify bone reorganization, increase bone density, and subsequently reduce fracture risk. Mineral and vitamin supplementation is also paramount and includes the combination use of calcium and vitamin D (Drake et al. 2012).

Rheumatoid arthritis

Definition

Rheumatoid arthritis (RA) is a disease characterized by chronic inflammation of the joints; however, adjacent tissues and other body organs (i.e. such as the skin, heart, lungs, and eyes) can also be affected. In this condition, the body's immune system has turned on itself and attacks the tissues and structures within the joints. While any joint can be affected by RA, the hands and feet are most commonly affected and have the greatest potential for leading to joint destruction and functional disability (Huizinga and Pincus 2010).

Pathophysiology

While the direct aetiology of RA is not well understood, several risk factors have been associated with the onset of an immune system reaction, including, a joint infection, trauma, and tobacco smoke. These immune system triggers cause the tissues within the joint to enlarge and cause inflammation; particularly among individuals who have a genetic disposition for immune sensitivity. Ultimately, the chronic inflammation in the joint leads to the destruction of various joint tissues, including cartilage.

Natural history

Epidemiologic studies have documented geographic variations in the prevalence of RA where it is found highest among Pima (5.3%) and Chippewa Indians (6.8%), and lowest among individuals from Japan and China (0.2–0.3%) (Helmick et al. 2008) These geographic variations in the prevalence of the disease further suggest that either a genetic or environmental component may be present (Silman and Pearson 2002). Population-based estimates suggest that approximately one-third of individuals with RA become work-disabled within 2 years of disease onset, and approximately 50% are work-disabled after 10 years (Combe 2009; JD 2010). Part of this disability and decrease in health-related quality of life is due to the physical, emotional, and social impact of the disease. While physician rating of patient pain is generally lower than pain self-reported by the patient, disease severity has been associated with the degree of pain experienced by the patient as well as their physical functioning.

Risk factors

Research studies have identified both modifiable and non-modifiable risk factors that contribute to the development of RA. In fact, a large proportion of RA cases are believed to arise from the interaction between genetic (i.e. non-modifiable) and environmental (i.e. modifiable) exposures. For example, the number of new RA cases is typically two to three times higher in women than men and the onset is highest among people in their sixties for both men and woman (Silman and Pearson 2002). Among modifiable risk factors include smoking, nutritional/dietary factors, infectious agents, and reproductive hormonal exposures (Pincus and Callahan 1993). Of these factors, tobacco exposure has been shown to be the strongest and most consistent in terms of being associated with RA, particularly among people who have specific immune markers in the blood (e.g. test positive for anticitrullinated protein/peptide antibodies) (Scott et al. 2010). Other studies have documented mixed evidence of an association between the use of oral contraceptives and a risk of RA (Brennan et al. 1997).

Treatment

Treatment options for RA can vary from the newest RA drugs to inclusion of exercise and NSAIDs as well as individualized care and management tips. There are two types of drugs used in treating RA, classified as first- and second-line medications. The first-line drugs include agents such as aspirin and steroids that are commonly used to reduce the person's pain and inflammation. Second-line drugs are slow acting and include the disease-modifying antirheumatic drugs such as methotrexate (i.e. Rheumatrex and Trexall), and hydroxychloroquine (i.e. Plaquenil) that thwart progressive joint disease and support remission. RA usually requires lifelong treatment, including medications, physical therapy, exercise, education, and surgical intervention depending on the disease severity (Ibrahim et al. 2012).

The scope of the problem

Thousands of millions of people suffer from MSD worldwide. The independence and autonomy of persons to do daily normal activities is affected by MSDs. The value in life that was going to be created by these sufferers can now be considered lost to society. Immeasurable suffering accompanies persons with MSDs and their families.

Families and society (e.g. government, industry) often contribute to social welfare and healthcare programmes that subsidize health services (Fransen et al. 2011).

Understanding and quantifying the magnitude of problem that MSDs bring to society is a difficult task (Caban-Martinez et al. 2011). Most cost estimations include only health expenditures and are available only for selected diseases and for some countries. On the other hand, measures based on disease occurrence (prevalence rates and proportion incidence) can offer a comprehensive overview of the problem in different geographical areas of the world, not without methodological difficulties (e.g. as MSDs have a slow onset, it is frequently hard to identify the moment when the disease starts).

A few important messages can be highlighted from the information available: (1) MSDs occur very frequently; (2) MSDs are expensive; (3) the extent of the problem of MSDs is increasing over time; and (4) There are important geographical differences in the distribution of MSDs.

MSDs occur very frequently

MSDs are among the most frequently occurring conditions in the population worldwide. The Global Burden of Disease (GBD) study estimates that 1,266 million people worldwide suffered from MSDs in 2016 (GBD 2016a, 2016b) Some of the conditions mainly affecting people are LBP, neck pain, and osteoarthritis (Table 8.9.1). Prevalence of musculoskeletal disorders has grown consistently from 15.1% in 1990 to 17.8% in 2016 (GBD 2016a, 2016b). It is important to consider, however, that not all MSDs were included in the study that produced these global estimations (Hoy et al. 2012).

Table 8.9.1 Point prevalence (in thousands) and prevalence rate of major musculoskeletal diseases in 2016 (GHDx, 2016)

MSD Type	Total		Males		Females	
	P	%	P	%	P	%
Low back pain†	511,048.2	7.18	229,687.0	6.47	281,361.2	7.88
Neck pain	290,524.0	4.08	123,233.5	3.47	167,290.5	4.69
Osteoarthritis	301,567.2	4.24	118,331.9	3.33	183,235.3	5.13
Other MSDs	337,859.3	4.74	136,523.4	3.85	201,335.9	5.64

† = Activity-limiting low back pain (+/– pain referred into 1 or both lower limbs) that lasts for at least 1 day.

Source: data from Hoy D., Bain C., Williams G., March L., Brooks P., Blyth F., Woolf A., Vos T. and Buchbinder R. (2012). A Systematic Review of the Global Prevalence of Low Back Pain. *Arthritis and Rheumatism*, 64, 2028–37.

MSDs are expensive

In 2011, the world spent a total of US$ 6.9 trillion in health-related expenses (WHO 2014). This figure includes government expenditures and out-of-pocket expenditures in health. An important part of this cost is attributable to MSDs where among developed nations they are responsible for approximately 25% of total expenses due to illness (Walsh et al. 2008). In addition, approximately 20% of regular primary care visits in the vast majority of countries is due to MSDs (Walsh et al. 2008). The pain experienced by individuals with MSDs is one the most common reasons for self-medications and for visits to a primary care setting. Among countries with ready access to medical care, MSDs account for a considerable number of healthcare visits and expenditures (Murray et al. 2012).

Most of data available in terms of monetary expenditures of healthcare is representative of specific geographical areas and specific MSD; most frequently in developed countries. In the State of Victoria, Canada for example, MSDs were the most frequent reason for outpatient visits to the medical centre (11.6% of the total) between 1997 and 2000. Also, among 26 medical specialties, MSD had the sixth highest number of inpatient episodes (6.2% in years 2000/01). In terms of costs, MSDs rank fifth in the number of bed-days away from work during the 1997 to 2001 period (Osborne et al. 2007).

These expenditures are not unique to Canada. An economic study on low back pain in the United Kingdom estimated that the direct costs of LBP were £1.6 billion in 1998. When factoring the indirect costs associated with LBP, countries such as Sweden (costs per capita: 24 US$ direct costs versus 266 US$ indirect costs, 8% versus

92%) and the Netherlands (24 US$ direct versus 299 US$ indirect, 7% versus 93%) had direct costs, lower than indirect expenditures spent in the United Kingdom alone. In the United States, data from the 1988 National Health Interview Survey documented that general LBP accounted for 149 million lost work days annually while work-related LBP accounted for 102 million work days lost. In total, all cases of LBP were estimated to cost about US$1,230 on average for men and US $773 on average for women with an annual productivity loss of $28 billion (Krismer and Van Tulder 2007).

The burden of MSDs is growing

The burden of MSDs is estimated using the disability-adjusted life years (DALY) metric of the GBD study. This metric aims to quantify how many years are lost due to disability (YLD) and due to mortality (YLL) for a list of hundreds of conditions, which are updated yearly. In simple terms, for example, if a person loses part of her capacity to perform daily activities due to a particular condition (disability weight of the condition), that person loses proportionally part of the years that she was going to live until her expected age of death. The sum of these two loses are the DALYs. For each condition, thousands of sequelae were identified. For example, for the condition 'LBP', four sequelae resulting from combining acute or subacute versus chronic pain, and pain in one or two legs versus without this pain were identified (Hoy et al. 2010a). YLDs are computed as the prevalence of a sequela times the disability weight for that sequel. The YLDs arising from a disease or injury are the sum of the YLDs for each of the sequelae associated with that disease. The value of these estimations roots on the fact that an attempt was made to achieve comparable figures for different geographical areas for two moments in time, years 1990 and 2016.

A few methodological aspects need to be highlighted in order to understand the DALYs: the years of life lost due to mortality are generally low due to MSDs. Part of it is because the chronic nature of these conditions, which causes that their effect is exerted through the loss of quality of life rather than to the loss of years of life. However, there are exceptions. For example, the death rate is increased for all osteoporotic fractures; however, while the death will be not be attributed to the underlying osteoporosis, it will be attributed to the injury. We also see this misclassification in other MSDs such as systemic vasculitis and untreated RA, where the death certificate will likely be labelled as death from end-organ failure or other comorbidity. As a consequence the metric does not fully capture the premature loss of life due to the individual living with the MSD. For conditions with low mortality rates such as osteoarthritis, there might actually be a greater burden of death due to the condition (Woolf et al. 2010).

The general distribution in the burden of disease has shifted from previously greater burden of communicable, maternal, and neonatal causes to non-communicable diseases including MSDs. In 1990, approximately 45.5% of DALYs were caused by communicable, maternal, and neonatal causes, 43.9% from non-communicable diseases, and 10.6% from injuries as compared to estimates in 2016 that had shifted to 27.9%, 61.4%, and 10.7%, respectively (GBD 2016a, 2016b). In absolute terms, worldwide the DALYs due to MSDs grew from 86.6 million ((63.1–112.7) in 1990 to 140 million (102.3–181.7) in 2016 (45% increase); or in relative terms from 1,645 (1,199.3–2,140.7) to 1,894.3(1,384.3–2,457.8) per 100,000 thousand persons (12% increase). These conditions would be responsible in year 2016 for 5.8% of the DALYs, which is a much larger share compared to the 3.6% estimated in year 1990 (GBD 2016a, 2016b).

From 1990 to 2016, the proportion of specific disease conditions in the MSDs has not changed significantly; however, LBP (41.2%), neck pain (20.7%) and osteoarthritis (11.6%) continue currently sharing the largest proportion of the pie among all MSDs in year 2016 (Table 8.9.1) (GBD 2016a, 2016b). Furthermore, LBP is the single MSD condition, which continues being the leading cause of all disability from 1990 to 2016; and has the highest age-standardized rates of YLDs in 133 of 195 countries and territories measured in the GBD study (Vos et al. 2012, 2017). Among DALYs, low back and neck pain combined, are 'the 4th leading cause worldwide in 2016, affecting primarily countries with middle, High-middle and High SDI, where it is the 4th, 3rd and 2nd leading cause', respectively (GBD 2016a, 2016b).

Differences across geographical areas for conditions such as LBP and neck pain are large, although concerns have been raised by the authors of the study regarding potentially methodological issues assigning for the case of neck pain, measurement error as spatial variation (Vos et al. 2017).

Musculoskeletal disease in absolute term is a larger burden for people between 40 and 49 years old (Table 8.9.2) (GBD 2016a, 2016b). However, it is clear that for males start being an important issue (considering all DALYs) as early as 10 years old in relation to other conditions at that age range, which is more or less maintained until the age of death; being one of the most important types of conditions in the range from 35 to 44. For women, MSDs start being important also at age of 10. In relative terms per 100,000 people, the burden remains stable since 1990 to

2016, but it increases monotonically by age until the age of 70–74 years, after which the burden stabilizes or slightly reduces (GBD 2016a, 2016b).

Table 8.9.2 DALYs (in thousands) and 95% confidence intervals related to major MSDs by selected age groups (both sexes) in year 2016

Cause	All age groups	35–39 years	40–44 years	45–49 years	50–54 years	55–59 years	60–64 years	65–69 years	70–74 years	75–79 years	80+ Year

(576 828.

Determinants of MSDs

Four risk factors can be considered major drivers of MSD occurrence worldwide: Obesity (Lim et al. 2012), ageing, the increase in trauma (particularly via road traffic collisions) (Walsh et al. 2008) and repeated mechanical loading (particularly via working conditions) (Lim et al. 2012). At another level of causation, behavioural changes related to diet and physical activity may be driving observed changes in obesity. Major determinants of these behavioural changes include technological development, income increase, globalization, growth of mass media and urbanization (Fig. 8.9.1).

Paradoxically, technological improvements have resulted in different consequences. On the one hand, medical advances and prevention of infant mortality (Anderson and Arias 2003) have made possible that the population ages have contributed to increase human life expectancy (Olshansky et al. 2005) contributing also in this way to ageing of the world population and therefore, to the occurrence of MSDs. Also, technological advances have made possible the reduction of physical demands (Popkin et al. 1989) at least for a part of the population, which may have also contributed to obesity and therefore to the occurrence of MSDs. Lastly, the lack of permeation of such advances in many industries contributes to the existence of large sudden physical demands or permanent low demands that are capable of promoting the occurrence or MSDs.

Other related factors include: (1) worldwide shifts in the trade of technology innovations that affect energy expenditures during leisure, transportation, and work; (2) globalization of modern food processing, marketing, and distribution techniques (most frequently linked with westernization of the world's diet); (3) vast expansion of the global mass media; and (4) other changes that constitute the rubric of the effects resulting from an increased opening of our world economy (Popkin et al. 1989).

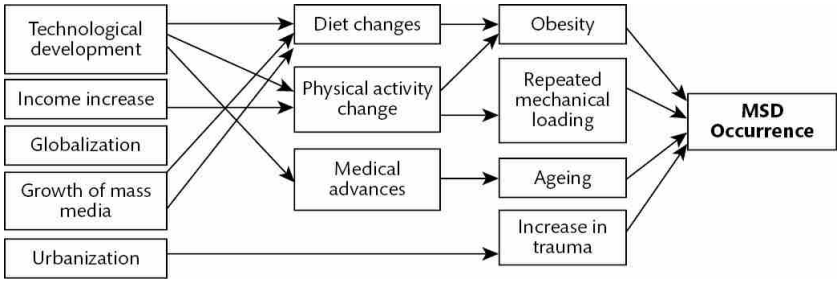

Fig. 8.9.1 Conceptual model relating the major determinants of musculoskeletal disorders.

Obesity

A major worldwide public health concern is the increasing growth of overweight and obese individuals in both developed and now developing countries. The DALYs of musculoskeletal disorders attributable to a high body mass index has been estimated by the Global Burden of Disease study. The most recent available report of this study indicated that for nearly all regions of the world, the burden of MSDs attributable to body mass index (BMI) has grown over the past few years. For the super region Central Europe, Eastern Europe, and Central Asia in 2016, the study attributed 225 DALYs of MSDs per 100,000 people to BMI, which is about 8.6% of all the DALYs per 100,000 people caused by MSDs in the same year. Between 1980 and 2008, the mean BMI (a proxy measurement for overweight and obese levels) worldwide increased by 0.4 kg/m² per decade for men and 0.5 kg/m² per decade for women. Gender and geographic differences in BMI status has been changing over the years. For example, male and female BMIs in 2008 were highest in specific Oceania countries, reaching 33.9 kg/m² for men and 35.0 kg/m² for women in Nauru. Female BMI was lowest in Bangladesh (20.5 kg/m²) and male BMI in Democratic Republic of the Congo 19.9 kg/m², with BMI less than 21.5 kg/m² for both sexes in a few countries in sub-Saharan Africa, and east, south, and Southeast Asia. The United States had the highest BMI of high-income countries. In 2008, an estimated 1.46 billion adults worldwide had BMI of 25 kg/m² or greater; of these 205 million men and 297 million women were obese (Finucane et al. 2011). From 1992 to 2000, using nationally representative data for women aged 20–49 years in 36 countries the proportion of overweight plus obese individuals exceeded underweight in most countries (Mendez et al. 2005). Even more concerning is the fact that the obesity problem in children matches the adult obesity, with the concomitant problems related to diabetes (Popkin 2006).

Multiple factors are contributing to this trend of increasing overweight and obesity worldwide, including most importantly physical activity and diet. Although there is significant variability between countries, it is true that around the world, diet and nutritional food consumption has become increasingly energy-dense and sweeter; and that processed foods are replacing foods that are high in fibre (Popkin 2006). On the other hand, the desire to reduce physical demands has always being an objective. In the advent of the information age, where more modern technologies are used in the workplace, in the shopping arena, and at home, there is likely to be decreased levels of physical activity. The picture of overall shifts in activity, their causes, and their consequences are still incomplete. Since the beginning of time, humans have made efforts to reduce physical effort in the home and at work. In addition, the growing demand for goods that are tasteful including portions higher in fat and sugars has been growing (Popkin et al. 1989). For example, the total calories ingested by US children age 2 to 19 increased on average from 2,065 calories in years 2003–2004 to 2,952 in years 2005_2008; while in adults there was a slight reduction from 2,170 to 2,106 for the same periods (Economic Research Service 2012).

The Economic Research Service (ERS) has conducted a series of studies that give interesting conclusions about the factors that influence diet decisions. Demographic factors (i.e. lower income, younger age, and lower formal education), household characteristics (single head of the household working parents) and acculturation (e.g. acculturated Hispanics), and misperceptions about quality of food at home, are related to lower quality diets or bad habits regarding their diets (skipping meals, eating away from home) (Economic Research Service 2012).

Ageing

The world population is ageing. The median of the world population has gone from 23.9 years in 1950 to 29.6 years in 2015 (Fig. 8.9.2). The population 60 or above worldwide has gone from roughly 202 million (8.0% of the total population) in 1950 to 906 million (12.3% of the total population) in 2015; and the population above 80 years

old went from roughly 14 million (0.6% of the total population) to roughly 126 million in 2015 (1.7% of the total population) (United Nations 2017).

The current median age of the population in Europe, Northern America, and Oceania are much above the world average. The growing trend in Europe is especially concerning as it is the current trend in Asia and Latin American and the Caribbean. In Asia, people over 65 have doubled from 6.8% in 2008 to 16.2% in 2004. It is expected that from 2008 to 2040, the proportion of people over 65 will grow 316% in Singapore, 274% in India, 269% in Malaysia, 261% in Bangladesh and 256% in Philippines. In 2008, Japan has the oldest population, and in absolute terms, China and India have the largest number of people over 65 (106 and 60 million) (Fransen et al. 2011).

This is also important considering that ageing is expected to increase the probability of comorbidity. One report from Scotland indicated that 64.9% of people between 65 and 84 years old suffer from comorbidity (Barnett et al. 2012). A recent review highlights the importance of musculoskeletal disorders as a pervasive component of comorbidity, capable of reducing disproportionally quality of life compared to other chronic conditions (Duffield et al. 2017). Naturally, the presence of comorbidity implies new challenges in terms of treatment accompanied with a significant increase in the cost of health services.

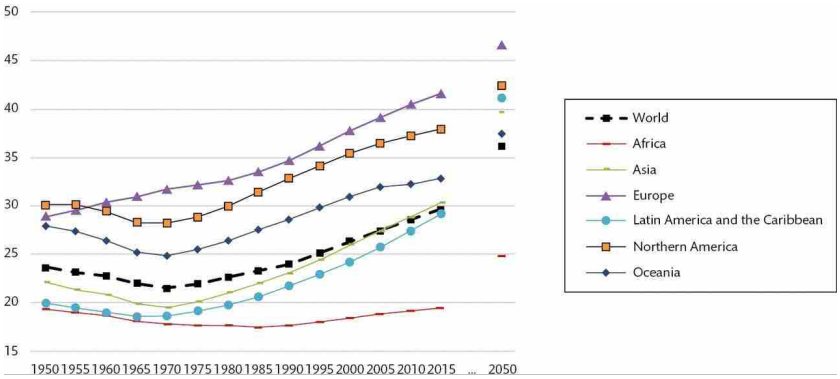

Fig. 8.9.2 Median age of the world population in the past decades and projection until year 2050.

Occupational factors

Although the importance of workplace factors as determinants of major MSDs such as LBP has been challenged (e.g. Coggon et al. 2018), the paradigm is still today that ergonomic conditions at the workplace can affect significantly the occurrence of this and other conditions, such as neck pain, and other upper-extremity conditions. The Global Burden of Disease study estimated that the DALYs per 100,000 people attributable to ergonomic factors ranged roughly in 2016 between 150 (for regions such as North Africa and Middle East, and Latin America and the Caribbean) and 275 (for the regions Central Europe, Eastern Europe, and Central Asia). It is, however, the regions North Africa and Middle East, and Latin America and the Caribbean are the ones growing in the past years since 1990 to 2016, from roughly 140 DALYs per 100,000 people to over 150 DALYs per 100,000 people.

Future directions

By now it should be clear that there are societal determinants of MSDs which act through several different complex pathways that give way to a significant increase in MSD occurrence, with important effects to human development and quality of life. To tackle such complex problem, different strategies are required at different levels (Fig. 8.9.3).

Policy level

Two actions that are non-specific to MSDs but are the platform for the health of the population are required: Redressing general social inequalities, including education, employment, housing, and food; and improving the

health financing system. Such actions are typically in the range of action of governments and the platform over which other actions are built. No health system alone will be able to address health inequalities if these factors are not addressed. According to the International Labour Organization (ILO), social security benefits that includes cover for lost wages in the event of illness is available to only one in five adults worldwide, and more than half of the world population lacks any form of social protection (ILO 1999; ILO 2000). For example, approximately 5–10% of adults in sub-Saharan Africa and Southern Asia as compared to 20–60% of middle-income countries have social security coverage. Recommendations in this regard have been given by the WHO. Country governments need to make sure that if people pay at the entrance of health services, those payments corresponds to their capacity of payment on a sliding scale. They also need to improve access and utilization of primary preventive services for the poor, despite the challenges of implementing such services in low-resource and economically strapped countries (WHO 2010).

Efforts to finance these types of systems should include especial attention to the need to better distribute available resources. Among Organization for Economic Cooperation and Development (OECD) countries there is a known 20/80 syndrome in which they spend over 80% of the world's resources on health yet make up less than 20% of the world’s total population. While only 6.5% of the African and 3.7% of South East Asian regions Gross Domestic Product (GDP) is spent on healthcare, OECS spend a much larger proportion on health (12.4%). Low-income countries with annual per capita income of less than US $1,005 relied most heavily on out-of-pocket payments to finance healthcare. In these countries the share of out-of-pocket payment in total health expenditure measured in US$ terms was 50% compared to only 13% in countries with incomes higher than US$12,276 per capita (WHO 2010).

Other important actions that are specific to MSD at the policy level are the creation and awareness of the scope of the MSD problem and investing in MSD research. Creating awareness is required so that action is started. Awareness moves political willingness. For example, the recent GBD study has placed LBP as the single leading cause of disability in year 2016 worldwide among 328 selected conditions assessed in this study (Vos et al. 2016). However, the health-related Sustainable Development Goals stayed focused on reducing mortality rather than the main causes of disability; and it has been postulated that tackling disability would be perceived as a more difficult task than tacking mortality (Vos et al. 2017). Nevertheless, the task persists; the information needs to reach and be understood by policy makers to prompt action. Efforts by the Bone and Joint Decade, a Global Alliance for Musculoskeletal Health have focused on raising this awareness of the burden of musculoskeletal conditions by developing sustainable networks and improving access to cost-effective prevention and treatment (Global Alliance for Musculoskeletal Health).

Healthcare systems are now confronted with the growing costs and increased prevalence of MSDs, that will require a coherent policy for dealing with MSDs. Identifying and prioritizing the research efforts on the most effective and affordable strategies for low-resource countries to deal with these conditions is paramount (Murray et al. 2012). The revealed outmost importance of MSDs should have consequences regarding the health system’s capital investments, especially to the light of an ageing population that will suffer comorbidity and considering too current trend in the increase of population BMI. As the expected future burden of MSDs grow, investment efforts into these cost-effective strategies will need to spread over a long-term outlook. In addition, training and educational efforts for the existing and entering healthcare workforce is urgently needed to adequately address the large group of individuals that will be afflicted with MSDs. Innovation in health professional education should include MSDs on a region by region basis, so that trends in demographic and epidemiologic change is fast enough that a forward looking assessment of the burden should be incorporate (Murray et al. 2012).
